INTERVIEW IN BEHAVIOURAL AND HEALTH SETTINGS

INTRODUCTION

The concept *interview* within a psychological assessment context is employed with two different meanings: as an information tool and, in a broader sense, as the professional interaction between client and psychologist. In this study, we will employ the concept to talk about the procedure to gather

information both in clinical and health contexts. In both cases, the interview is the most used tool when a verbal interaction takes place between a professional and a client (or clients). The interview has a main goal: to obtain the maximum information possible in order to develop a functional analysis. This analysis will provide the basis to understand and to modify the problem when necessary. On the other hand, the interview, in addition to the use of questionnaires, is the only procedure available currently to obtain information on a client's cognitive responses, verbal-cognitive in this case (thoughts, attributions, belief system, etc.). Furthermore, it constitutes an economical tool to assess psycho-physiological responses (throbbing, muscular tension, etc.). Also, the interview is cheaper than the use of psycho-physiological devices, even though it is an indirect method (assessing the subjective perception that the client has).

In spite of its usefulness and popularity, only a few studies have analysed its reliability and validity. However, these studies obtained discouraging results (Hay, Angle & Nelson, 1979; Felton & Nelson, 1984).

DEFINITION

A clinical interview can be defined as the procedure followed by a professional (psychologist-interviewer) in a conversation with one person or more (clients) with the goal of getting desired information. Accordingly, it can be stressed that the basic interview characteristics within an assessment procedure are the following:

- An interaction between two or more people.
- A two-way route verbal communication.
- Some goals previously established by the interviewer who controls the procedure and withdraws the information from the interviewee.

In sum, the main goal of the interview as an assessment tool is to obtain information in order to build the behaviour-problem's functional analysis. In order to reach this goal, there should be followed several steps (Table 1). First, the problem description should be pursued in the most objective way available (behavioural, cognitive and psycho-physiologic responses). Secondly, the quantitative parameters that define the problem

Table 1. General interview guidance

1 Behaviour-problem delimitation
   - Problem identification
   - Problem description (behavioural, cognitive and psycho-physiologic responses)
   - Description of the last incident
2 Behaviour-problem parameters
   - Frequency (maximum and minimum)
   - Intensity (maximum and minimum)
   - Duration (maximum and minimum)
   - Recent frequency, duration or intensity of the behaviour-problem
3 Behaviour-problem determinants
   - Description of the situation/context in which the problem occurs
   - What does the client do when the behaviour-problem starts and finishes?
   - How do surrounding people react when the problem starts and when it finishes?
4 History of the behaviour-problem from its start
   - When was the problem first displayed and under what characteristics and parameters?
   - Evolution of the problem through its start until today
   - Differences and similarities between then and now
5 Impact of the behaviour-problem
   - How does the problem affect the client's life?
   - How does the problem affect other people around?
   - Client's motivation to solve the problem
6 Expectations and goals
   - Causal attributions
   - Personal or professional actions and intervention to solve the problem
   - Results obtained in the past
   - Recent expectations to solve the problem
   - What does the client expect?

should be specified and, thereinafter, delimitated antecedent and consequent elements in order to establish the behaviour functionality (antecedent stimuli, conditioned and/or discriminative and consequent stimuli and reinforcements). Once the fundamental aspects of the problem are assessed for current incidents, the history and the evolution of the problem should be inquired, as well as its impact in the client's life.

The interview should be displayed in a directing but flexible way. It should have an initial-facilitating phase (exploratory); an intermediate phase for clarification and specification; and a final phase focused on solving doubts and assuring congruency on the obtained data with the client. It is important to take into account that the interview is essentially an active interaction process between two or more people. Regardless of the goal of gathering information, the interview itself may also have therapeutic effects on the client. Therefore, it is critical to assure that the communication process is effective as a critical aspect to develop positive boundaries with clients. That is to say, when the treatment includes behavioural aspects, it is essential that the client is ready to accomplish the prescribed assignments to solve the problem. Therefore, a good communication and comprehension between professional and client should be maximized. Professional skills such as the ability of providing information, offering confidence, showing comprehension, operating management and, in sum, displaying basic technical and social abilities (therapeutic skills) are critical in order to develop an interview within a clinical or health assessment.

The language used by the professional during the interview has to be culturally adapted to the interviewee. As time goes by, the interviewee will acquire a behavioural language through a modelling and moulding process. Thus, the client will facilitate the required information with precision.

Another important aspect during the development of the interview is to collect the obtained information. Recording the information with an audiovisual device would be the best technique because it may allow registering of either verbal or non-verbal content. Another frequently used alternative is taking notes simultaneously while the client speaks. However, this method to collect information is somewhat problematic because it can impede and jeopardize the communication fluency. In addition, the professional may also lose important pieces both of verbal and non-verbal contents.

The client's role during the interview should be active and collaborative, even though it is the psychologist's responsibility to reach these goals by using his/her therapeutic skills (communication and operating management).

The interview completion requires a summary of the obtained information in order to guarantee its veracity according to the client's judgement. Eventually, it is usually required to complete the information with other evaluation procedures, especially questionnaires and the use of direct observation when possible within clinical and health assessment contexts.

FUTURE PERSPECTIVES

There was an attempt to outline the utility of the interview as a behavioural evaluation procedure during the 60s. In spite of the efforts accomplished to systematize the interview (Haynes, 1978; Linehan, 1977) during the 70s, it was not until the 90s that the importance of developing more investigation to identify the relative efficiency of the various components, procedures and strategies of the behavioural interview was taken into account. Recent discoveries led to a change that will affect both the evaluation and the therapy, in relation to the importance of verbal exchanges within a behavioural clinical context. From this perspective, investigations on verbal behaviour, especially from an operative conditioning perspective, represent one of the most fruitful lines on scientific psychology (Hayes, 1989). Taking in account that the interview is essentially a verbal exchange (regardless of the importance of non-verbal communication acts), studies focused on verbal behaviour are of high interest.

CONCLUSIONS

The interview is the most employed assessment procedure. However, its psychometrical properties have not been specified yet neither has the most effective method to carry it out. The main goal is to obtain relevant information on the behavioural sequence (what constitutes the problem to study and solve) in order to develop a functional analysis. Being an interpersonal

exchange of communication, it is not appropriate to neglect the importance of the communication proficiency (therapeutic skills) as well as the therapeutic effects that, independently of the assessment goal, may occur during the communicative exchange. The psychological interview is mainly directing, being the interviewer responsible to evoke relevant information in order to assess the problem.

INTERVIEW IN CHILD AND FAMILY SETTINGS

INTRODUCTION

Interview can be defined as a system of communication, typically dyadic, aimed at acquiring information. The interview is a basic tool in many social sciences, including psychology. In every field of child psychology, from basic research to professional practice, sooner or later one will be faced with the task of discovering what a child thinks, feels or knows. Nevertheless, the validity of the interview (and more generally the use of verbal protocols; see Praetorious & Duncan, 1988) is continually debated, especially with children (Bruck & Ceci, 1996).

Interviewing is dangerously similar to everyday conversations. In fact, asking and answering are basic human activities (Flammer, 1981), which take place in the most varied occasions: a dialogue between friends, a school exam, a medical interrogation, a police questioning, and so on. In each of these situations, the communicative exchange is set by implicit, yet powerful rules (Schenkein, 1978). Some of these regulative factors apply to every dialogue, such as the need of turn taking, or the looks which signal the onset and the end of the verbal exchange; other rules, such as the degree of interpersonal distance, vary from one culture to another; still others, such as the degree of politeness required or the reciprocity of roles, depend on the characteristics of the partners and the content of the dialogue. We apply all these non-written rules based on tacit assumptions about speakers' roles and aims, and children more than anyone else do it unknowingly. It is hence clear that the first step towards interviewing well is to know the nature of this particular kind of verbal exchange, and to make it clear to the interviewees.

INVESTIGATIVE AND CLINICAL INTERVIEWS

Psychological interviews can be grouped in two broad classes, each roughly associated with some

general characteristics. In the first class – investigative interviews – we can include all the interviews aimed exclusively at discovering some respondent's mental contents, for research or forensic purposes. The second class comprises all kinds of clinical interviews, in which the need of obtaining useful information for the diagnosis is intertwined with that of establishing a therapeutic alliance. Investigative interviews are associated with: the interviewer as a main beneficiary of the obtained information; a strategy of non-interference with the interviewee's ideas and feelings; a preference for standardized formats. Clinical interviews are associated with: the interviewee as a main beneficiary of the given information; a legitimate intervention in the interviewee's ideas and feelings; a preference for highly flexible formats.

In practice, psychological interviews often escape such a clear-cut classification. For instance, with young children the maximum of possible standardization can be a list of contents to be orderly followed since it is necessary to adapt the actual phrasing to the child's language, attention span and tolerance for the interview situation as a whole.

Investigative interview techniques were first developed in the context of research about cognitive development. Piaget (1926) explained how it is possible to use interview as reliable sources for studying children's ideas, but he also outlined how easy it is to come up with useless answers. Children can answer randomly, if poorly motivated, tired, bored; or they can produce myths and fantasies, if they treat the interview as play; or they can parrot the interviewer's suggestions. Piaget's generalized guidelines on how to conduct valid interviews were incorporated in the research paradigm stemming from his work. Only recently, however, systematic studies have become common, especially under the pressure of the increasing number of child witnesses in legal cases of abuse or controversial parental custody (Pool & Lamb, 1998). In fact, legal court and psychological research are among the few situations in which children can be irreplaceable sources of information.

Clinical interviews with children and parents are an integral part of child psychoanalytic and psychiatric treatment (A. Freud, 1966; Winnicott, 1971; Sullivan, 1954; Rutter, Taylor & Hersov, 1994). In these contexts, three categories of patients can be distinguished: co-operative patients, who openly talk about their problems; 'resistant' patients, who conceal part of their problems; and patients unaware of their problems (Othmer & Othmer, 1994); accordingly, the interviewer is forced to use more direct questions to obtain relevant information. It is also clear that children belong more frequently to the third category, as they are often unaware that communicating certain experiences could help solve their problems; hence more guidance is needed when children are interviewed for diagnostic purposes. Moreover, it is always necessary to validate the information so obtained with data from other sources, usually parents and sometimes other figures (other relatives, teachers) (AA.VV., 1997). Direct observation during play sessions, or in everyday settings (e.g. school), is recommended with young children.

ESTABLISHING SETTINGS

In both investigative and clinical interviews, the first methodological precaution is to create an appropriate setting. The ambience should be pleasant and stimulating, but not too rich with distracting objects; it should be equipped for videotaping if testimony has to be collected. Some simple toys for symbolic play and materials for drawing and moulding should be at hand, depending on the child's age.

Children are often unaware of the reasons for their having been brought to the consultation, or (worse) they are led to believe that some unpleasant medical procedure would take place. In a simple and encouraging way, the interviewer must explain the aim of the questions, guarantee confidentiality and reaffirm the child's right to not answer. In the case of legal interviews, some authors also recommend ascertaining whether the child can distinguish between truth and lying (McGough, 1994), but the best ways to reach this goal are still a question of debate (Pool & Lamb, 1998). Instead, it has been experimentally demonstrated that children provide a larger proportion of correct answers about a previously witnessed event if they are told in advance that the adult does not know what happened and that they can answer 'I don't know' when appropriate (Mulder & Vrij, 1996). Another useful practice, in the preliminary phase of forensic interviews, is

to enhance the remembering of past events with the instructions provided by the 'Cognitive Interview' (Geiselman, Saywitz & Bornstein, 1993).

BUILDING A RELATIONSHIP AND BEGINNING THE INTERVIEW

A familiarization phase with the child is always necessary. For instance, in a clinical setting, it is not always opportune to begin the interview talking about symptoms. Talking for a while about neutral matters helps the child to develop a sense of self-assurance and trust (Angold, 1994), while the interviewer can appraise the child's communicative abilities. With young children playing or drawing can help break the ice. In forensic interviews, the child can be asked to talk about a recent, non-related event (Pool & Lamb, 1998). In clinical consultations, when the child or the adolescent arrives accompanied by parents, who will be also interviewed, it is necessary to give complete assurance that his/her point of view is important and will be respected as much as that of the adults.

STRUCTURING THE INTERVIEW

Some clinicians point to the advantages of open, non-directive interviews ('client-centred', Rogers, 1945, 1951) while others claim superior merit for structured interviews in one or another of their numerous formats (many of which are listed in AA.VV., 1997). It has been noted, however, that no interview can be really 'non-directive': it is sufficient for the clinician to smile or take notes to reinforce some answers (Cox & Rutter, 1985). It is better to manage explicitly the situation than to risk selectively distorting the child's answers under the influence of those 'confirmatory biases' widely documented by social psychology and inevitably as much present in the interviewer's as in anyone else's.

The choice of a structured interview does not necessarily imply abandoning personal initiative. This can be true for highly structured interviews ('respondent-based') but not for semi-structured interviews ('interviewer-based') (Angold, 1994) in which a series of key questions are listed, some of which can be omitted, while others can be elaborated in depth. In diagnostic settings, the course of the interview will depend on two key factors: the subject's age (see Barker, 1990) and the 'decisional tree' adopted by the clinician (analytical examples in Harrison & Eth, 1998). Investigative interviews can be highly structured when they are conducted for research purposes (but not necessarily so, *cf*. Lumbelli, 1993), and less structured in forensic contexts.

ASKING QUESTIONS

Questions are 'open' when they allow for a wide range of answers, and 'closed' if they admit only yes or no answers or allow for choosing between a few, ready-made options (multiple choice questions). The principal merit of open questions is that they reduce the interviewer influence. Interviewers should be aware that materials derived from interviews are rarely 'spontaneous'. When based on children's reflections about topics they had not considered before, answers are, at best, genuine, but 'provoked' (Piaget, 1926). Open questions are widely used in the legal field, to obtain narrative accounts of allegations. Young children, however, are not very productive in answering open questions, and resorting to closed questions in order to cover all relevant aspects is almost inevitable. Besides a correct setting, productivity can be enhanced by techniques such as mirroring (Rogers, 1945) or non-specific verbal prompts such as 'tell me all that you have seen' or 'all you have heard' (Elichsberger & Roebers, 2001).

EVALUATING ANSWERS

In clinical assessment, the conclusions drawn from an interview should be always conceived as hypotheses, verification of which relies on the continuing therapeutic process. The situation is different with investigative interviews, where the validity of the protocol should be in itself evident enough to be used as a proof. Methods of content analysis for evaluating protocols have been developed (Steller & Koehnken, 1989), based on the assumption that truthful narratives of events are different from inventions or biased descriptions (Undeutsch, 1982). Recent studies

(Orbach & Lamb, 2001) have shown that leading questions generate more contradictions than open, non-leading questions. Contradictions, then, can be used as indices of a poor interview and not only (or not always) of the interviewee's uncertainty or reticence.

AVOIDING ERRORS

Conversation in everyday contexts is a robust communicative tool, since participants can go back over unclear subjects in order to achieve reciprocal understanding. Adults capitalize on this when talking with children, often using new terms or complex linguistic forms (double negatives, passive verbs, subordinates) as occasions for linguistic apprenticeship (Wertsch, 1985). In an interview, instead, difficult or obscure forms should be carefully avoided, especially with young children. Misunderstandings that are easily remedied in everyday situations can create serious problems in an interview. For instance, if one includes two questions in a single utterance, children usually answer only one, and it can even be impossible to detect which one they have actually responded to (Walker & Hunt, 1998).

Some conversational styles are also sources of error in interviews. With children it is common to use rhetorical questions that are in fact orders ('would you please get up?') or suggestions ('it's a nice toy, isn't it?'). Not only should this kind of leading question be avoided, but it is also necessary to make clear to the child that there are no 'right answers' to guess. It is also safer to avoid repeating the same question, a way of talking which is often used in everyday life as a strong suggestion to change answer, and in fact has been found to elicit contradictions from young interviewees.

When it becomes necessary to resort to closed questions, multiple choice questions which allow a 'content' answer should be preferred to those eliciting yes–no alternatives, to avoid the effect of any subjective bias towards answering always yes (or always no) in case of doubt.

And above all, one should be aware that memorizing this list of errors, or a series of good practices, does not transform anybody by magic into an expert interviewer (Sternberg et al., 2001). On the contrary, only a long apprenticeship joined with deep intellectual honesty and a vibrant interpersonal sensitivity can help a person acquire the difficult art of interviewing children.

FUTURE PERSPECTIVES AND CONCLUSIONS

The interview is undoubtedly one of the most important psychological tools, and it promises to be employed in the future as much as it has been used during a century of psychological research practice. Perhaps the interview will become even more necessary, if the present popularity of cognitive theories does not decline, since these theories almost invariably require discovering the subject's perspective. The recognition that young children are most competent knowers than they were previously thought to be is another factor which has increased the population of potential interviewees, and this trend is likely to continue. The difficulty of avoiding suggestions and other mistakes while verbally interacting with preschoolers has led psychologists to refine the interviewing techniques, taking into account memory and language problems, as well as social roles as sources of bias. These advances will be beneficial for interviewing other 'special populations' such as immigrant adults with limited linguistic skills, or mentally retarded people. Most important, a new wave of experimental research on the interview has begun, which is especially concerned with the validity of interviews in forensic settings. It would be important if this effort of refinement and validation were to be developed to cover still other aspects of interviewing and extended to a wider variety of fields of application, including diagnostic and clinical. Finally, how to teach interviewing to psychology students and young practitioners is a question that requires special attention indeed: no instrument can be fully appreciated without those people capable of using it at its best.

INTERVIEW IN WORK AND ORGANIZATIONAL SETTINGS

INTRODUCTION

This entry describes the central results of research on the selection interview. After a definition of the interview in psychological assessment main features of selection interviews are described. Prerequisites of psychological interviews are given and the central developments in the area of the selection interview are summarized. Then the results of meta-analyses on reliability and validity of selection interviews are presented. Finally conclusions and future perspectives on selection interviews are given.

DEFINITION

A psychological interview is a kind of conversation between one or more interviewers and one or more interviewees which follows implicit and explicit rules and aims at gathering information for the description, explanation or prediction of individual behaviour or the relationship between people, or at gathering information about the conditions that change or stabilize individual behaviour or the relationship between people.

FEATURES OF SELECTION INTERVIEWS

Most frequently, one person interviews another. A group of interviewers interviewing one applicant is called a panel or a board. A psychological interview has the following three sections: (a) planning, (b) realizing, and (c) summarizing. Rules for realizing the interview are very often agreed at the beginning of a psychological interview. These rules relate for example to aims, duration, themes, recording and summarizing of the psychological interview. In addition, both interview partners behave according to implicit rules for a conversation. All conceptions of psychological interviews which lead to psychometrically acceptable interview results have an explicit planning in common. Thus, these interviews are (at least partially) structured or completely standardized. In partially structured interviews the questions are prepared; in structured interviews, the sequence of questions is also prescribed. In standardized interviews, furthermore, explicit rules are given concerning all relevant conditions for realizing and summarizing the interview.

PREREQUISITES

In all fields of applied psychology, the abilities of interviewers have been initially overestimated and the complexity of planning, realizing and summarizing an interview have been systematically underestimated. If interviewers want to arrive at satisfying decisions, i.e. not to regret later the low procedural quality in these decisions, the following prerequisites must be fulfilled. They (a) need to plan an interview systematically and to base it on empirically well founded research results, (b) must be well trained individually in realizing an interview, and (c) must summarize, after individual training, the results of an interview according to explicit rules.

DEVELOPMENTS

In the last five decades there has been an increasing tendency to structure selection interviews. In addition to this, a growing number of selection interviews are founded on basic theoretical notions. The Situational Interview (Latham et al., 1980) is based on goal setting theory and its basic assumption is that people behave according to their goals. In contrast to this interview conception, the (Patterned) Behaviour Description Interview (Janz, 1982) is, like the Experience-Based Interview (Pulakos & Schmitt, 1995), based on the assessment prediction rule that the best predictor of future

behaviour is past behaviour. In traditional selection interviews, personality traits were assessed. This, however, did not prove to be very useful. More valid information results from selection interviews based on a requirement profile derived from an empirical job analysis. Selection interviews of the 'third generation', e.g. Schuler's (e.g. 1989) Multimodal Interview, combine all these measures relatively successfully.

RELIABILITY AND VALIDITY OF SELECTION INTERVIEWS

Reliability

Because reliability defines the upper limit of validity, Conway et al. (1995) published a meta-analysis on the reliability of the selection interview. Interview reliability is higher for panel interviews than for individual interviews, higher for trained interviewers than for untrained interviewers, and higher for highly structured interviews than for those with a lower degree of structuring. Structure was operationalized by three dimensions: standardization of questions, standardization of response evaluations (global rating vs. multiple-dimension ratings vs. ratings for each answer) and standardization of method for combining ratings (subjective vs. mechanical). Conway et al. (1995: 573–574) found that 'Estimates of upper limits of validity were 0.67 for highly structured interviews, 0.56 for moderately structured interviews, and only 0.34 for interviews with low structure. These upper limits represent the highest validities that could be achieved with a perfectly reliable criterion.' McDaniel et al. (1994: 604) reported higher mean reliability coefficients: 0.68 for unstructured interviews and 0.84 for structured interviews.

Validity

Hunter and Hunter's (1984) often cited meta-analysis found a validity coefficient of 0.14 for the selection interview. In contrast to this, later meta-analyses based on many more studies and people revealed that the 'received doctrine' of interview invalidity is false (Wiesner & Cronshaw, 1988). Structured selection interviews were found to have higher validity than unstructured interviews (Wiesner & Cronshaw, 1988; McDaniel et al., 1994; Huffcutt & Arthur, 1994). Furthermore, Huffcutt and Arthur (1994: 184) found that 'Interviews, particularly when structured, can reach levels of validity that are comparable to those of mental ability tests. Although validity does increase through much of the range of structure, there is a point at which additional structure yields no incremental validity. Thus, results suggested a ceiling effect for structure.' Mental ability tests are usually seen as the predictors with the highest validity. Structured selection interviews in particular can be as valid as mental ability tests (Huffcutt & Arthur, 1994). Contrary to widespread opinion, the results of a meta-analysis indicate that individual interviews are more valid than board interviews whether they are structured or not (McDaniel et al., 1994). The use of job-analytic information for the preparation of an interview yields higher validity coefficients (Wiesner & Cronshaw, 1988), which also accords with the data of Conway et al. (1995). Contrary to a variety of earlier studies, Wiesner and Cronshaw (1988) in their meta-analysis did not find any moderating effect of the sex and race of rater or ratee.

Reliability of Criteria

Validity of selection interviews can be evaluated by the application of criteria like success in training, job performance or tenure. These criteria are more reliable than psychiatrists' diagnoses, but they are far from being perfect in reliability and validity, which must be taken into account in meta-analyses. In meta-analyses, the lack of reliability in estimates of these criteria is used for assessing the true validity of selection interviews. Recent studies on the reliability of these criteria show, however, that they are better than estimated (e.g. Rothstein, 1990). This allows the conclusion that validity of selection interviews is underestimated by the meta-analyses.

Incremental Validity

There is a widespread opinion that selection interviews mainly assess verbal intelligence. The studies of Campion et al. (1994) and Schuler et al. (1995), however, indicate that selection

interviews can have incremental validity beyond that of cognitive tests, i.e. a correlation remains between interview data and criteria even when intelligence has been held constant. Both studies used carefully prepared interview guides based on an empirical job analysis, and standardized questions of the situational interview type as well as questions of the behaviour description type. Additionally, the interviewers had to evaluate as well as combine the answers according to explicit rules.

FUTURE PERSPECTIVES AND CONCLUSIONS

After ten years of meta-analytical work, we can state that a well structured selection interview based on empirical job analysis can measure highly reliable predictors which cannot be measured by tests. There are a lot of hints on the potential influence which interindividual differences of interviewers and interviewees can have on the selection interview result (for an overview see Graves, 1993), but these differences seem to be of no practical influence in highly structured interviews (Pulakos et al., 1996).

The following question must still be answered: what constructs can be assessed only by interviews or more efficiently by interviews than by other methods? (See Conway et al., 1995; Pulakos & Schmitt, 1995; Roth & Campion, 1992; Schuler, 1989).

IRRATIONAL BELIEFS

INTRODUCTION

Cognitive-behavioural assessment is a technique used to test the thought processes which define many psychological disorders. A major component of cognitive-behavioural assessment is the measurement of irrational thoughts and beliefs. The tests of irrational thinking developed thus far have grown out of the work of American clinical psychologists Albert Ellis and Aaron Beck.

IRRATIONAL BELIEFS IN CLINICAL PSYCHOLOGY

Albert Ellis developed rational-emotive therapy (RET), now known as rational-emotive-behaviour therapy (REBT), during the 1950s as a result of his discontent with the efficacy of psychoanalysis (Ellis, 1962). The main hypothesis of REBT is that beliefs about events are the most important cause of appropriate or self-defeating emotions and behaviours. REBT is based on the ABC model of psychopathology, in which unpleasant activating environmental events (A) do not cause undesirable emotional and behavioural consequences (C); instead they are caused by the irrational beliefs (B) held about the event.

Irrational beliefs are beliefs by which external events are interpreted which are absolutistic and self-defeating observations. They are self-statements, unlikely to find empirical support, that reflect unspoken assumptions about what is necessary to lead a meaningful life. In a person holding irrational beliefs, inevitable setbacks will lead to inappropriate negative behaviours and emotions. Rorer (1989: 484), in describing the absolutistic nature of these beliefs, referred to them as 'beliefs that the world or someone or something in it should be different than it, she, or he is, because one wants it to be'. One very common irrational belief noted by Ellis is that people believe they must be completely competent in everything they do. When an inevitable error is committed, it becomes catastrophic because it is a violation of the belief in personal perfection.

Another version of the ABC model was provided by Beck (1976). According to Beck's theory, numerous disorders are caused and maintained by negative thinking styles and negative beliefs that people have about themselves, their current circumstances, and the future. Included among these cognitive errors are assuming excessive personal causality for negative events, and thinking of the worst believing that it is most likely to happen. These cognitive errors, referred to as distortions, guide the interpretation of new experiences and increase vulnerability to psychopathology.

The theories of both Ellis and Beck describe the logic of people with behaviour disorders as faulty in that they make exaggerated negative inferences about what happens to them. However, recent research suggests that for REBT, demandingness, thinking that someone or some circumstance must be a certain way rather than preferring that something be a certain way, is the main quality of all irrational beliefs. It is in this way that the theories of Ellis and Beck differ; for REBT disorders occur if beliefs are demanding rather than preferential (McDermut, Haaga & Bilek, 1997).

The aim of REBT is to eliminate self-defeating beliefs via cognitive restructuring. Therapists forcefully dispute clients' irrational beliefs by questioning the evidence for the belief. The eventual goal is the integrating of cognitive, affective, and behavioural processes in order to bring about the desired therapeutic result. As in the case of REBT, the goal of Beck's cognitive therapy (CT) is to alter systematic errors in logic or misinterpretations about events which predispose an individual to develop pathological behaviours. Consequently, accurate assessment of irrational beliefs is essential for treatment. Perhaps more importantly, as REBT and CT are receiving increasing empirical scrutiny, valid measures of irrationality are necessary to furnish evidence of their scientific status.

EARLY MEASURES BASED ON THE ELLIS MODEL

Initially, assessment of irrational thinking was conducted via clinical interviews, which owing to problems with replication, are not appropriate for research purposes. The first objective measures were based on Ellis' (1962) original list of 11 specific irrational ideas. Nearly all tests of irrational beliefs are in the form of questionnaires.

Irrational Beliefs Test (IBT)

Jones (1968) developed the 100-item IBT which requires subjects to indicate their level of agreement or disagreement with each of the 100 items on a 5-point scale (such as 'I frequently worry about things over which I have no control'). Half of the items indicate the presence of a particular irrational belief, the other half its absence.

Adult Irrational Ideas Inventory (AII)

The AII (Fox & Davies, 1971) is a 60-item scale for adults based on an earlier version for children developed by Zingle (1965). The response mode is a four-point Likert scale, from 'strongly agree' to 'strongly disagree'. Item statements were presented so that strong agreement was sometimes very irrational and sometimes very rational.

Self-Inventory

The Self-Inventory (Plutchik, 1976) is a 45-item scale in the form of simple statements that can be answered 'Yes' or 'No' in terms of self-descriptions. The Self-Inventory was designed as both a therapeutic screening and evaluation index, and a research instrument. A German questionnaire, the *Fragebogens Irrationaler Einstellungen* or FIE (Joorman, 1998), includes translations of items used in the Self-Inventory.

Rational Behaviour Inventory (RBI)

Developed by Shorkey and Whiteman (1977), the 38-item RBI was designed as an instrument for treatment planning and assessment of REBT clients. The answers range, on a 5-point Likert scale, from 'strongly agree' to 'strongly disagree'. There are 11 rationality factors plus a total score; the higher the score, the more rational the person is.

Idea Inventory

The Idea Inventory (Kassinove, 1977) is a 33-item 3-point Likert scale, with each of Ellis' 11 irrational beliefs measured by three items. All items are presented as an irrational idea; consequently any disagreement represents rational thinking. The questionnaire results in a total irrationality score plus scores on each individual belief.

Articulated Thoughts in Simulated Situations (ATSS)

ATSS (Davison, Robins & Johnson, 1983) is unlike the questionnaire format of previous measures of irrationality in that it provides a constant analysis of participants' thoughts while they imagine themselves in four negative or stressful scenarios. Narrated events are presented via audiotape; respondents vividly imagine that the events are happening to them. The respondents' thoughts are taped and later evaluated for irrationality.

SECOND GENERATION MEASURES BASED ON THE ELLIS MODEL

Despite their widespread use, subsequent research has questioned the discriminant validity of many of these early measures in that they appear to be confounding irrational beliefs with negative affect. More recent measures have been designed to maximize discriminant validity by excluding items consisting of emotional statements.

Belief Scale (BS)

Malouff and Schutte (1986) created the 20-item BS, with the intention of devising a scale which was shorter and which had more construct validity than previous measures (no items asked about anxiety reactions). Respondents indicate the degree to which they agree with 20 statements on a 5-point Likert scale ranging from 'strongly disagree' to 'agree strongly'.

General Attitude and Belief Scale (GABS)

Burgess (1986) developed a 96-item measure of irrationality which excluded items referring to behavioural or emotional consequences. Bernard (1990) established a 55-item version of the test (on a 5-point scale), which provides a total irrationality score, six irrationality subscales, and one rationality subscale. The GABS was again shortened to form the 26-item shortened GABS or SGABS (Lindner, Kirkby, Wertheim & Birch, 1999).

Survey of Personal Beliefs (SPB)

The SPB (Demaria, Kassinove & Dill, 1989) is a 50-item self-report scale scored on a 5-point Likert format. It was created as a measure of irrational beliefs free of affectively worded items. Further, the test items reflect more recent conceptualizations of irrational beliefs. The SBP assesses Ellis' four core irrational beliefs of awfulizing, demandingness, low frustration tolerance, and self/other rating (shoulds) as well as providing a total rationality score.

Irrational Beliefs Inventory (IBI)

This 50-item scale developed by Koopmans, Sanderman, Timmerman, and Emmelkamp (1994) is based on the item pool of the IBT and the RBI. The IBI, answered via a 5-point scale, consists of five subscales plus a total irrationality score. The IBI is distinguishable from negative affect in that it measures cognitions rather than anxiety or depression.

BECK'S COGNITIVE MODEL

Central themes of Beck's cognitive model of psychopathology are dysfunctional attitudes (shoulds and musts) and cognitive errors in response to negative life experiences. These errors are interpretations and predictions which are not justified by the information provided. Beck's model led to the development of measures designed to assess these negative thinking styles and dysfunctional beliefs.

Dysfunctional Attitude Scale (DAS)

The DAS (Weissman, 1979) is a 100-item measure, answered on a 7-point Likert scale from 'totally agree' to 'totally disagree'. It identifies beliefs that might interact with a stressor to produce psychopathology. The short form devised by Dyck (1992) comprises 56 items representing 8 subscales. This form provides an indication of the general level of dysfunctional thinking as well as specific types of dysfunctional thought represented by the individual subscales. Lower scores represent greater maladaptive thinking.

General Cognitive Error Questionnaire (CEQ)

The General CEQ (Lefebvre, 1980) was designed to measure cognitive errors or distortions related to general life experiences. The General CEQ consists of 24 short vignettes followed by a dysphoric cognition about that vignette. Vignettes were categorized according to four cognitive errors identified by Beck, including catastrophizing and personalizing. Respondents are asked to rate how similar the cognition is to the thought they would have had. The 5-point rating scale ranges from 'almost exactly like I would think' to 'not at all like I would think'.

FUTURE PERSPECTIVES AND CONCLUSIONS

Many early measures of irrationality remain in use. The IBT and RBI remain popular tests and are frequently cited in the research literature. This is despite criticisms that the questionnaire versions are dated (they reflect Ellis' earlier theories of irrational thinking), and because they do not measure irrational beliefs independently of the affect they were theorized to cause. Second generation tests based on the Ellis model are recognized as having higher discriminant validity because they do not refer to affect in their items. The DAS and CEQ based on Beck's model are regarded as valid measures of irrationality and continue to be cited frequently as well.

REBT and CT are based on theories which are continuously evolving due to rigorous research on the role of irrationality in behaviour disorders.

Both have shown that they are receptive to research findings. Similarly, as theory changes, the measures of irrationality have changed as well. The SPB (Demaria et al., 1989) reflects changes in REBT from 11 irrational beliefs to 4 core ideas. Newer measures will continue to be created to further test the thesis that there is a relationship between behaviour and irrational beliefs. These measures will have enhanced content validity by aligning item content with theoretical changes.

There are several areas of future concern in which irrational beliefs assessment will play a key role. They include: (1) discovering if specific types of irrational thinking are associated with specific disorders; (2) paying particular attention to the evaluation of change in irrationality due to treatment; (3) studying the effect of cultural influences in the development of irrational beliefs; and (4) determining if rational training prevents psychological disorders.

ITEM BANKING

INTRODUCTION

Item banks are used in a variety of contexts ranging from individual classrooms, schools, districts, state or other governmental units, to large scale computer-based testing programs. Typically, the purpose of developing an item bank is to assist, improve, and automate the test assembly process. In developing an item bank, a number of decisions about two factors need to be considered. These factors are the design of the bank and the methods for maintaining and refreshing it once it has been created.

Designing an item bank is analogous to creating a database. At the simplest level, the designer must decide what data elements to store and then how to structure the data in order to facilitate data extraction and reporting, test assembly, and possibly even test administration functions. For item banks these functions are realized through item selection and test assembly processes. Item selection and test assembly processes can be placed into two broad categories: one in which human intervention is heavily relied upon and another in which automation is heavily relied upon (e.g. through the use of computerized algorithms). Each of these approaches place differing requirements on an item bank. Ultimately, if a bank is to be used to assist humans in the assembly process, the challenges of building the bank are less difficult to meet. This is in contrast to the context in which tests must be administered directly from a bank without human intervention, requiring full automation of the test assembly process.

A typical item bank contains four classes of information about each item: (a) the actual item text and associated graphical or stimulus material, (b) some classification information about the item characterizing its non-statistical properties such as relevance to educational standards, cognitive processes required to produce a successful solution and content, (c) some form of statistical and performance data about the item, and (d) some representation of the history of an item's use.

BANK DESIGN

Most automated test assembly algorithms rely on item statistics that have been placed on a common scale. Although transformations of the proportion correct (Gulliksen, 1950) and biserial correlations can be used, the most popular of these are based on Item Response Theory (IRT, Lord, 1980). In fact, the majority of literature on the topic of item banking has focused on methods and procedures for developing and maintaining an IRT scale. The interested reader might find the December 1996 volume of *Applied Psychological Measurement*, a special issue dedicated to item banking, helpful, and papers by Rudner (1998) and Flaugher (2000).

For traditional paper-and-pencil tests, assembled in advance of test administration, the amount of item classification data stored is relatively small. Although by no means incomplete, the data elements stored tend to be the minimum set required to guide a human assembly of a test with the added assumption that the test will be reviewed and revised before use. For a Quantitative measure, this might include:

(a) Math Content – Arithmetic, Algebra, Geometry, or Calculus
(b) Level of Context – Pure Math or Word Problem
(c) Response Format – Multiple Choice, Short Answer, or Numeric Entry
(d) Correct Answer

A number of features tend not to be stored. These include many aspects of the item's content that only became an issue with respect to other items assembled into a single test. For example, in a Verbal measure, the fact that a reading passage is about the works of Charles Dickens is typically not a feature that is stored or even explicitly considered. If two passages about Dickens are selected in a draft assembly, a human reviewer would note this and one of the passages would be replaced. As a second

example, two Analogy items might rely on the test taker knowing the definition of 'inflammable'. It is generally considered unacceptable practice to include multiple items in the same test that rely on specific vocabulary. Here again, key vocabulary is not typically an attribute that is stored for each item. Other types of interactions between items rely on global human impressions rather than extensive item classifications. For example, it might be found that a test is well within statistical specifications, but that a test reviewer has the impression that this collection of items is unusually time consuming to complete.

As test assembly becomes dynamic and performed in real time during a test administration it becomes necessary to codify, at the item level, every aspect of a form that should be controlled. This requires a priori specification of every item property of concern. While this seems relatively intuitive for the examples above, when extended to controlling the number of references about medical conditions, colours, boats, etc. in a test, it becomes apparent that the complexity and richness of the classification scheme is the key to the success of item bank development.

Historically, these item properties and their interactions with each other have been evaluated by having a human actually perform all pairwise comparisons and identify those items that should not appear in the same test. This avoids the need to delineate all of the specific features that would be of concern and to identify whether each item does or does not have the feature. While a viable, albeit time consuming, practice when banks contain hundreds of items, this practice becomes untenable when banks include thousands of items. Every addition to the bank requires a redefinition of the lists of items that should not appear together. Thus, as the bank becomes large, management of these lists becomes intractable and the information becomes stored in a classification scheme as a list of features that the item does or does not have.

With on-demand testing, it has become necessary for the lag between uses of an item to become smaller. Most testing programmes simply don't have the resources to have a new test or pool in the field every day. This introduces a number of security concerns. Way, Steffen and Anderson (1998) detail one method for mitigating the potential risks of this practice. The core idea is to reuse items only when necessary and then restrict use, to the degree possible, to items that were seen by fewer test takers than other items. The implications of any such plan for an item bank is that it is now necessary to track the complete history of usage for every item. That includes any pool to which the item has been assigned, the administration period of that pool, and the number of test takers delivered the item during that administration period.

BANK MAINTENANCE/ REFRESHMENT

There are a number of commercially available software packages that perform all of the functions described above, including the IRT calibration/scaling functions (e.g. CAT Builder [2001], FastTEST [2001]). However, the effective use of an item bank requires careful consideration of a number of issues that software cannot address. This includes deciding how often to augment or refresh the bank, what types of items to write, when items should be retired, what kinds of content and statistical reviews should precede an item's entry into the bank, how many items should be included in the bank, and an item tryout/calibration plan so that new items can be screened, calibrated, and scaled.

Performance standards for including items in the bank can take a variety of forms. For paper-and-pencil testing programmes, these criteria typically involve some classical item analysis statistics (Henrysson, 1971). The proportion correct cannot be too high or too low, some minimum level of item-total score correlation is required as well as empirical verification that there is only a single correct response. For IRT-based programmes, this is usually done with some form of model-data fit statistic (Kingston & Dorans, 1985; Thissen, Steinberg & Fitzpatrick, 1989). Adaptive testing programmes also add criteria about the magnitude of the parameters themselves. For example, with maximum information item selection, items with discrimination parameters that are low (e.g. less than 0.40) have virtually no chance of being selected for administration. Thus, if resources allow, these items might be discarded. More recently, computer-based testing programs have begun to incorporate criteria for item latencies into the item screening process. Based on item tryout data, it is

possible to identify items that require inordinately more time to answer than other items that have similar content and statistical characteristics. These items are actually discarded, thus reducing the risk that tests that appear parallel to the assembly algorithm are differentially speeded.

On-demand pool-based testing programmes have been exploring the issues of minimum bank size for several years. The concerns focus mainly on security issues. Unfortunately, definitive answers have yet to appear in the literature; we simply do not know how often an item can be administered before its subsequent performance is altered.

Refreshing a bank is conceptually straightforward. The goal is to create at least as many new items as are retired. The difficulty is anticipating which items will be retired. For linear paper-and-pencil testing programmes this is relatively easy since items in a test form are retired as a unit, and specifications are constant across forms. However, for adaptive testing programmes, items are not used equally. In order to obtain desired levels of measurement precision with fewer items, adaptive algorithms seek to deliver highly informative items at higher rates than in paper-and-pencil tests. Additionally, high and low performing test takers are administered a greater number of items with extreme difficulty than typically appear in a single paper-and-pencil test. In order to avoid administering the same items to all of these examinees, large numbers of items of extreme (high and low) difficulty are needed. These tend to be the most challenging items to develop.

FUTURE PERSPECTIVES AND CONCLUSIONS

An item bank can be a powerful support tool for test development activities. However, the creation of an item bank is not an activity to be undertaken lightly. It is important to keep in mind that item banks are developed to support a test assembly algorithm. The constraints imposed by an algorithm should influence, if not determine, the decisions made about the design and maintenance of the item bank. Clearly, more research on topics such as the optimal design of item banks, item selection, and the maintenance of item banks can be expected in the coming years.

ITEM BIAS

INTRODUCTION

Methods for detecting differential item functioning (DIF) and item bias typically are used in the process of developing new measures, adapting existing measures, or validating test score inferences. DIF methods allow one to judge whether items (and ultimately the test they constitute) are functioning in the same manner in various groups of examinees. In broad terms, this is a matter of measurement invariance; that is, is the test performing in the same manner for each group of examinees? What follows is a brief introduction to DIF and item bias, including the context in which DIF methods arose. The goal is to provide some organizing principles that allow one to catalogue and then contrast the various DIF detection methods. This entry will end with a discussion of current and future directions for DIF.

CONTEXT IN WHICH DIF METHODS AROSE

Concerns about item bias emerged within the context of test bias and high-stakes decision-making involving achievement, aptitude, certification, and licensure tests in which matters of fairness and equity were paramount. Historically, concerns about test bias have centred around differential performance by groups based on gender or race. If the average test scores for such groups (e.g. men vs. women, Blacks vs. Whites) were found to be different, then the question arose as to whether the difference reflected bias in the test. Given that a test is comprised of items, questions soon emerged about which specific items might be the source of such bias.

Given this context, many of the early item bias methods focused on (a) comparisons of only two groups of examinees, (b) terminology such as 'focal' and 'reference' groups to denote minority and majority groups, respectively, and (c) binary (rather than polytomous) scored items. Due to the highly politicized environment in which item bias was being examined, two inter-related changes occurred. First, the expression 'item bias' was replaced by the more palatable term 'differential item functioning' or DIF in many descriptions. DIF was the statistical term that was used to simply describe the situation in which persons from one group answered an item correctly more often than equally knowledgeable persons from another group. Second, the introduction of the term 'differential item functioning' allowed one to distinguish item impact from item bias. Item impact described the situation in which DIF exists because there were true differences between the groups in the underlying ability of interest being measured by the item. Item bias described the situations in which there is DIF because of some characteristic of the test item or testing situation that is not relevant to the underlying ability of interest (and hence the test purpose).

Traditionally, consumers of DIF methodology and technology have been educational and psychological measurement specialists. As a result, research has primarily focused on developing sophisticated statistical methods for detecting or 'flagging' DIF items rather than on refining methods to distinguish item bias from item impact and providing explanations for why DIF was occurring. Although this is changing as increasing numbers of non-measurement specialists become interested in exploring DIF and item bias in tests, it has become apparent that much of the statistical terminology and software being used is not very accessible to many researchers.

FRAMEWORKS FOR CONSIDERING DIF

At least three frameworks for thinking about DIF have evolved in the literature: (1) modelling item responses via contingency tables and/or regression models, (2) item response theory, and

(3) multidimensional models. Although these frameworks may be seen as inter-related, they are freestanding. Each framework provides useful organizing principles for describing DIF and developing methods for detecting DIF in items.

MODELLING ITEM RESPONSES VIA CONTINGENCY TABLES AND/OR REGRESSION MODELS

A statistical implication of the definition of DIF (i.e. persons from one group answering an item correctly more often than equally knowledgeable persons from another group) is that one needs to match the groups on the ability of interest prior to examining whether there is a group effect. That is, the definition of DIF implies that after conditioning on (i.e. statistically controlling for) the differences in item responses that are due to the ability being measured, the groups still differ. Thus, within this framework, one is interested in stating a probability model that allows one to study the main effects of group differences (termed 'uniform DIF') and the interaction of group by ability (termed 'non-uniform DIF') after statistically matching on the test score.

This class of DIF methods, in essence, consists of conditional methods in that they study the effect of the grouping variable(s) and the interaction term(s) over-and-above (i.e. while conditioning on) the total score. In this sense, they share a lot in common with analysis of covariance (ANCOVA) or attribute-by-treatment interaction (ATI) methods. Building on this similarity, it is important to recognize that nearly all DIF methods are applied in what would be called an observational or quasi-experimental study design and so one must keep in mind all of the commonly known caveats around making causal claims of grouping variable effects in observational studies involving intact groups.

This framework for DIF has resulted in two broad classes of DIF detection methods: Mantel–Haenszel (MH) and logistic regression (LogR) approaches. The MH class of methods (Holland & Thayer, 1988) treats the DIF detection problem as one involving, in essence, three-way contingency tables. The three dimensions of the contingency table involve (a) whether one gets an item correct or incorrect, (b) group membership, while conditioning on (c) the total score discretized into a number of category score bins. The LogR class of methods (Swaminathan & Rogers, 1990) entails conducting a regression analysis (in the most common case, a logistic regression analysis as the scores are binary) for each item wherein one tests the statistical effect of the grouping variable(s) and the interaction of the grouping variable and the total score after conditioning on the total score. One clear contrast between the MH and LogR methods is that one needs to discretize the conditioning variable in the MH methods whereas one does not have to do so with the LogR methods. The MH assumes no interaction (like ANCOVA) whereas the LogR allows for an interaction (like ATI methods).

ITEM RESPONSE THEORY

Referring back to the definition of DIF in the previous section, one can approach DIF from an item response theory (IRT) framework. In this case, one considers two item characteristic curves (ICCs) of the same item but computed from two groups. In the IRT context, if the items exhibit DIF, then the ICCs will be identifiably different for the groups. The ICCs can be identifiably different in two common ways. First, the curves can differ only in terms of their threshold (i.e. difficulty) parameter and hence the curves are displaced by a shift in their location on the theta continuum of variation. Second, the ICCs may differ not only on difficulty but also on discrimination (and/or guessing) and hence the curves may be seen to intersect. Within this context, the former represents uniform DIF (i.e. a main effect of group) whereas the latter represents non-uniform DIF (i.e. an interaction of group by ability).

In its essence, the IRT approach is focused on determining the area between the curves (or, equivalently, comparing the IRT parameters) of the two groups. It is noteworthy that, unlike the contingency table or regression modelling methods, the IRT approach does not match the groups by conditioning on the total score. That is, the question of 'matching' only comes up if one computes the difference function between the groups conditionally (as in MH or LogR). Comparing the IRT parameter estimates or ICCs is an unconditional analysis because it implicitly assumes that the ability distribution has been

'integrated out'. The mathematical expression 'integrated out' is commonly used in some DIF literature and is used in the sense that one computes the area between the ICCs *across the distribution* of the continuum of variation, theta.

A problem occurs in the IRT context because it is a latent variable modelling approach. Because the scale for theta in any IRT model is arbitrary, one must set it during calibration. How is this resolved? Computing algorithms like BILOG (and other such 2PL/3PL varieties of calibration software) set the mean of the ability distribution at zero. Some Rasch calibration software typically set the mean of the item difficulties at zero whereas others fix a single item parameter estimate, much like one does in confirmatory factor analysis to fix the scale of the latent variable.

The issue that arises in DIF is that if the two groups have different ability distributions, then the scales for the groups will be arbitrarily different. This is a problem because, in the case of DIF, one wants the two groups on the same scale or metric. If the two groups are not on the same metric, any DIF results will be impossible to interpret. This matter of a common metric is important to highlight because, in several recent studies, some Rasch analysts have ignored this matter and computed the difference between the item difficulty parameter for the two groups with a t-statistic, falsely relying on Rasch invariance claims to justify the computation and incorrectly ignoring the need for a common metric.

Because it is also relevant to the multidimensional framework that follows, more detail is provided on how to establish a common metric. In many IRT applications, one way to do this is to estimate the item parameters for a subset of items common to each group and use these item parameters to estimate abilities on the common metric. Then, one recalibrates the items, one at a time, for each group using this common metric. The most appropriate way of doing the DIF analysis is to leave the item(s) of concern out of the calibration, estimate the abilities on the common metric (without being influenced by the response patterns of the item(s) of concern), and then do the separate calibration of just the studied item using the uncontaminated ability estimates as fixed values that 'anchor' the scale.

The most common IRT methods for DIF include: signed area tests (which only focus on uniform DIF), unsigned area tests (which allow for non-uniform DIF), and nested model testing via a likelihood ratio test, which is most easily conducted for uniform DIF. In addition, one can approach this via non-parametric IRT using the software TestGraf (Ramsay, 2001). An advantage of non-parametric IRT is that it provides a graphical method and needs far fewer items and subjects than other IRT approaches.

MULTIDIMENSIONAL MODELS

There has been a longstanding framework for DIF based on the dimensionality of items. This framework begins with the assumption that all tests are, to some extent, multidimensional. The informal rationale has been that there is typically one primary dimension of interest in a test but there may also be other dimensions within that test that produce construct-irrelevant variance. For example, in a problem-based test of mathematics, the test will consist of some primary dimension that reflects mathematics ability as well as some other dimensions that may reflect other secondary abilities such as reading comprehension or verbal abilities. These other dimensions are often correlated with the primary dimension. As part of this informal rationale, it was not uncommon to think of DIF as arising from dimensions other than those of primary interest in the test. Ackerman (1992) provides a thorough discussion of the basis for the multidimensional framework.

Stout and his colleagues (e.g. Shealy & Stout, 1993) formalized some of this thinking and introduced a new DIF test statistic, simultaneous item bias test (SIBTEST) based on their framework. The multidimensional approach to DIF, as implemented in SIBTEST, allows for a variety of scenarios that comprise differential dimensionality as the source for DIF. Because this method involves a type of factor analysis, it requires the analyst to study sets (or bundles) of items, rather than individual items, for DIF.

Because the multidimensional framework, like IRT, is a latent variable approach, it must be noted that the above discussion regarding the importance of a common metric and how one establishes a common metric using subsets of items also applies

to the multidimensional approach. This similarity is often overlooked in the literature.

A FINAL COMMENT ON THE THREE FRAMEWORKS

Although the three frameworks are freestanding, as a set they have provided a powerful lens for describing DIF, developing statistical methods for detecting DIF, and thinking about the sources of DIF. As a final layer to cataloguing and contrasting the various DIF methods, the first framework described above can be seen to use observed score methods (because MH and LogR generally condition on the observed total score) whereas the latter two frameworks are latent variable approaches.

CONFIRMATORY VERSUS EXPLORATORY METHODS

Each of the above sets of methods could be used in a confirmatory or exploratory manner. That is, as has been noted by the proponents of the multidimensional approaches to DIF detection, the conventional manner in which one investigates DIF is to individually examine all items on a test for DIF and then, if the results suggest DIF, those items are further studied by content specialists and others to ascertain possible reasons for the observed DIF and determine whether item impact or bias is present. Given that such DIF studies usually occur in the context of observational (rather than experimental) studies, the sources or causes of DIF may be difficult to establish. Thus, the conventional approach is an inductive or exploratory approach to investigating DIF.

Alternatively, one could approach the DIF detection issue from a more theory-based and hypothetico-deductive strategy. That is, one would consult (with the aid of a content specialist) the relevant literature and determine whether any predictions (i.e. scientific hypotheses) can be made for where and why and for who DIF may be present. Once this has been accomplished, one then goes about testing the predictions using any of the DIF detection methods. The attractiveness of this strategy for many is the hope that a theory-based approach will provide an explanation for why DIF would be present (i.e. from a multidimensional framework, the literature would identify the secondary dimension(s)) and whether the DIF reflects item impact or bias. Of course, the confirmatory (i.e. theory-based) strategy is most fruitful when the content literature is well developed.

FUTURE PERSPECTIVES

The direction and focus of DIF research has been shaped by its origins in test bias and high-stakes decision-making involving achievement, aptitude, certification, and licensure tests. Current directions in DIF research find their inspiration from considering many testing situations outside of test bias, per se. Today, in addition to matters of bias, DIF technology is used to help answer a variety of basic research and applied measurement questions wherein one wants to compare item performance between or among groups when taking into account the ability distribution. At this point, applications of DIF have more in common with the uses of ANCOVA or ATI than test bias per se.

This broader application has been the impetus for a variety of current and future directions in DIF development, such as test translation and cross-cultural adaptation. Many novel applications of DIF occur because previous studies of group differences compared differences in mean performance without taking into account the underlying ability continuum. An example of such an application in language testing would be a study of the effect of background variables such as discipline of study, culture, and hobbies on item performance.

Moving beyond the traditional bias context has demanded developments for DIF detection in polytomous, graded-response, and rating scale (e.g. Likert) items. Furthermore, because DIF methods are being used increasingly by non-measurement specialists, it has been necessary to develop more user-friendly software and more accessible descriptions of the statistical techniques as well as more accessible and useful measures of DIF effect size for both the binary and polytomous cases.

Finally, ongoing research is focusing on complex data situations wherein one has students nested within classrooms, classrooms nested within larger school organizations, and a myriad of contextual variables at each level that are potentially related to DIF. New methods are being developed to study the contextual variables while remaining true to the complex data structure with random coefficient models and generalized estimating equations.

CONCLUSIONS

It is important to note that in this entry we have focused on 'internal' methods for studying potential item bias, i.e. within the test or measure itself. It is important for the reader to note that there is also a class of methods for studying potential item bias wherein we have a predictor and criterion relationship in the testing context. For example, in some industrial and organizational contexts, one has a test that is meant to predict some criterion behaviour. Item (or, in fact, test level) bias then focuses on whether the criterion and predictor relationship is the same for the various groups of interest.

ITEM RESPONSE THEORY: MODELS AND FEATURES

INTRODUCTION

Educational and psychological testing has been undergoing major changes in recent years. Demands for new psychological measures, increased interest in diagnostic assessment, the influence of cognitive psychology on testing, introduction of new test item formats, and the role of computers in test administration, scoring, and score interpretations are five of many changes taking place in testing practices today. Less well known among psychologists is the fact that the basic psychometric theory for developing educational and psychological tests and evaluating tests and test scores is changing too and these changes should make the construction and evaluation of tests and the interpretation of test scores easier and potentially more valid.

Psychologists have seen occasional references to the Rasch model, the three-parameter logistic model, latent trait theory, item response theory,

latent ability, item characteristic curves, computer adaptive testing, etc. in popular psychological testing texts, test manuals, and journals (see, for example, Anastasi, 1989). These new psychometric terms are associated with modern test theory, known as 'item response theory'. The purposes of this entry are (1) to describe some of the shortcomings of classical test theory, models, and methods, (2) to introduce item response theory and related concepts and models, and (3) to identify some of the advantages of item response theory and associated methods for psychologists.

SHORTCOMINGS OF CLASSICAL TEST THEORY AND METHODS

Classical test theory has provided the statistical underpinnings for both educational and psychological tests. While popular psychological testing books such as those of Thorndike and Hagen, Anastasi, and Cronbach do not provide the relevant theory and derivations, all of the popular measurement formulas and approaches for constructing tests, evaluating tests, and interpreting scores that appear in these books (e.g. Spearman–Brown formula, standard error of measurement, corrections for score range restrictions) are derived from the classical test model.

Despite the usefulness of classical test theory and models in psychometric methods, shortcomings in the basic theory underlying psychological testing and measurement procedures for test construction have been recognized for over 50 years (see Gulliksen, 1950). One such shortcoming is that classical item statistics – item difficulty and item discrimination – depend on the particular examinee samples from which they were obtained. A consequence of this dependence on a specific sample of examinees is that these item statistics are only useful when constructing tests for examinee populations that are similar to the sample of examinees from which the item statistics were obtained. Unfortunately, one cannot always be sure that the population of examinees for whom a test is intended is similar to the sample of examinees used in obtaining item statistics. Preferable would be statistics for test items which are independent of the particular sample of examinees in which they are obtained. 'Invariant item statistics over samples' is the goal.

Not only are popular classical item statistics used in test development samples dependent, but so are other important test statistics such as test reliability and validity. Test reliability is higher when estimated in heterogeneous samples of examinees rather than in more homogeneous samples of examinees. Correction factors are often used to adjust reliability estimates for this problem but the fact is that the dependence of reliability indices on the choice of examinee sample is troublesome. Again, test statistics independent of examinee samples would be valuable.

A second shortcoming of classical test theory is that comparisons of examinees on the test score scale are limited to situations where examinees are administered the same (or parallel) tests. The seriousness of this shortcoming is clear when it is recognized that examinees often take different forms of a test or even different sections within a test. For example, one medical board requires candidates to take a 'core section' and then three of six additional sections of the test. Examinees are compared using scores based on a test consisting of the core and three optional sections. Since the sections are not equally difficult and there are twenty different combinations of three sections possible, comparisons among candidates become difficult. In fact, it is *not* fair to require the same passing score for candidates who have been administered tests that differ, perhaps substantially, in difficulty. When several forms of a test that vary in difficulty are used, examinee scores across non-parallel forms are *not* comparable unless one makes use of equating procedures, which are often quite complex.

There are many situations where the use of non-equivalent tests are of interest. Out-of-level achievement testing in schools is one example. More effective administration of a battery of aptitude tests by adapting the battery to the examinee's ability is another. Starting examinees at different points in an intelligence test based on some prior information about the examinee is another example. But these examples create a problem at some point and that is examinees who have taken different forms of the test needed to be compared to each other, or to a norm group

who took a different version of the test. As test scores are sample dependent (test scores depend on the set of items administered), they are not an adequate basis for score reporting or using norms tables, when examinees are administered tests that are non-equivalent in difficulty.

A computer-adaptive test (CAT) is another excellent example of the problem of item dependent scores. A CAT is a test administered by a computer, where the items administered are dependent on the candidate's performance on previous items: perform well and the computer selects harder items; perform poorly and the computer selects easier items. But, again, the non-equivalence of test forms makes comparisons among examinees or comparisons of examinees' test scores to passing scores difficult without the use of complex equating methods. Other shortcomings of classical test models have been described by Hambleton and Swaminathan (1985) and Hambleton, Swaminathan, and Rogers (1991).

What is needed, if the goal is to tailor or adapt the administration of tests to examinees, is an approach to ability estimation which is not test dependent. The influence of the particular items on the test administered to the examinee needs to be accounted for.

ITEM RESPONSE THEORY

Frederic Lord and Harold Gulliksen from the Educational Testing Service in Princeton, New Jersey, and many other psychometricians in the 1940s and 1950s, were interested in producing a psychometric theory by which to assess examinees in a way which did not depend directly on the *particular* items which were included in a test. The idea was that an examinee may score high on an easy test or lower on a hard test, but there is a more fundamental ability that the examinee brings to any given testing situation which does not change as a function of the sample of items administered. It is that more fundamental characteristic of the examinee which is usually of interest to the psychologist and it is that more fundamental characteristic, referred to as a 'latent variable', which is of interest in modern test theory. This construct of interest is more fundamental than test score because ability unlike test score does not change with the particular choice of items in a test. It could change, however, over time, because of instruction, life changes, experiences, etc.

Ability is the term used by psychometricians to describe the construct measured by a test. It might be verbal or numerical ability, intelligence, creativity, or mathematics achievement. It might also be self-esteem, achievement motivation, or attitudes about school. The label 'ability' is used to describe whatever construct validation studies have shown that a test measures.

Item response theory (IRT) purports to overcome the shortcomings of classical test theory by providing a reporting scale on which examinee ability (the construct measured by the test) is independent of the particular choice of test items administered. What began in the 1940s and 1950s as a goal of psychometricians, became reality beginning in the 1960s and 1970s. By the early 1970s, the theory was developing nicely, computer software was available, and applications of IRT were beginning to appear. Today, IRT is well developed and being used by test publishers, large testing agencies, test developers, and researchers to address technical problems such as the design of tests, the study of item bias, equating test scores, and computer-adaptive testing.

IRT, in its basic form, postulates that (1) underlying examinee performance on a test is a single ability or trait, and (2) the relationship between the probability that an examinee will provide a correct answer (or agree to a statement, in the case of a personality or attitude survey) and the examinee's ability can be described by a *monotonically* increasing curve. We would expect examinees with more ability to have a higher probability of providing a correct answer than those with less ability so this feature is highly desirable. Or in the case of (say) an instrument measuring student attitudes towards a topic, we would expect those persons with very positive attitudes to agree with a statement more frequently than those persons with less positive attitudes.

The curve representing the relationship between the probability of a correct response and ability is called an 'item characteristic curve' (ICC). Figure 1 shows the item characteristic curve for the three-parameter logistic model which can be applied to test items scored 0 or 1. Each item in the model is described by three parameters: the *c*-parameter is the probability of

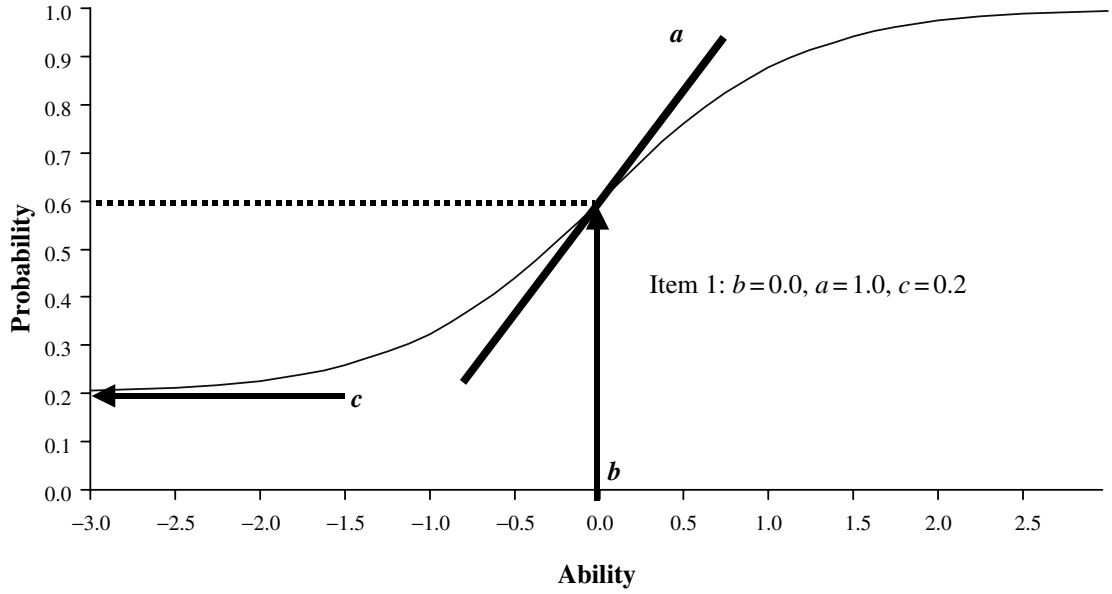

Figure 1. A typical item characteristic curve for the three-parameter logistic model.

low-performing examinees answering an item correctly by guessing (0.20 is a typical value), the *b*-parameter is the point on the ability continuum where an examinee has a probability of $(1 + c)/2$ of giving a correct answer (this parameter corresponds to item difficulty in the classical test model), and the *a*-parameter is proportional to the slope of the curve at the point b on the ability continuum (this parameter corresponds to item discrimination in the classical test model). The particular values of the item parameters for any item determine the exact shape of the ICC. The choice of IRT model dictates the mathematical form of the ICCs and the number of item parameters in the model. With highly discriminating items, the kind of item a test developer wants, the ICCs are very steep; for easy items, the ICCs are shifted to the left end of the ability scale, and for hard items, the ICCs are shifted to the right end. It is typical to scale ability scores to a mean of zero and a standard deviation of one in research work. For score reporting, a more convenient scale is used – one without decimals and negatives.

ICCs for dichotomously scored items (e.g. correct/incorrect or true/false) are typically described by one, two, or three parameters. The number of parameters identifies the IRT model. With the popular Rasch model, or one-parameter model, items are described by a single item parameter, called the 'item difficulty statistic'. This would mean that all of the test items would have the same shape, but the items could vary in their difficulty. With the two- and three-parameter models, items have more degrees of freedom for fitting data – but with improved fit and flexibility, come complications in parameter estimation.

Figure 2 highlights another attractive feature of IRT models. It is the concept of 'item information'. Here, the contribution an item makes to the precision of ability estimation at each ability level can be determined. The item shown in Figure 2 will be most effective for estimating ability of examinees in the interval, say, between about −0.50 and 1.0. The sum of the item information curves for items selected in a test produces the test information curve which indicates the precision of ability estimation at each point along the ability continuum.

Within an IRT measurement system, ability estimates for an examinee obtained from tests which vary in difficulty will be the same, except for the usual measurement errors. Some samples of items are more useful for assessing ability, and therefore the corresponding errors associated with ability estimation will be smaller. But the ability parameter being estimated is the same

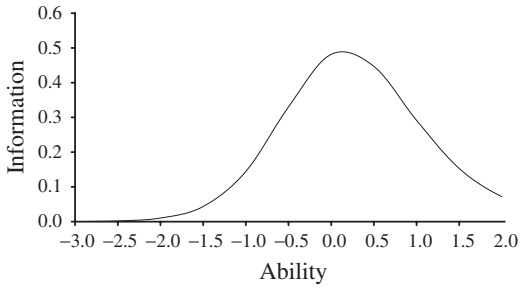

Figure 2. The item information curve corresponding to the item characteristic curve shown in Figure 1.

across items unlike in classical test theory where the person parameter of interest, true score, is test dependent. This invariance feature in the ability parameter is obtained by incorporating information about the items into the ability estimation process. Sample invariant ability estimates are of immense value in testing because tests can be matched to the ability level of examinees to minimize errors of measurement and maximize test appropriateness, while at the same time, comparisons in ability scores can be made because the ability estimates are *not* test dependent.

The concept that ability and item parameters do not change as a result of different samples of persons and items is known as *ability parameter invariance* and *item parameter invariance*, respectively. In theory, this is because when the item parameters are estimated, ability estimates are used in the item parameter estimation process (which is not the case in classical test theory). Also, when examinees' abilities are estimated, item parameter estimates are incorporated in that process (again, this is not the case in classical test theory). Both ability estimates and item statistics are reported on the same scale, so they look different from classical test scores and item statistics. Finally, IRT provides a direct way to estimate measurement error at each ability estimate (score level). In classical test theory, it is common to report a single estimate of error, known as the standard error of measurement, and apply that error to all examinees. Clearly, such an approach is less satisfactory than producing an error estimate at each ability score level.

IRT models (e.g. the one-, two-, and three-parameter logistic models) provide both invariant item statistics and ability estimates. Both features are of considerable value to test developers because they open up new directions for assessment such as adaptively administered tests and item banking. Of course, the feature of *invariance* will not always be present. Item and ability parameter invariance will be obtained when there is (at least) a reasonable fit between the chosen IRT model and the test data. Not surprisingly, then, considerable importance is attached to determining the fit of an IRT model to the test data. This point is addressed briefly in the next section.

There are IRT models to handle nominal, ordinal and equal-interval educational and psychological data: one-, two-, and three-parameter normal ogive and logistic models; partial credit and graded response models; multidimensional normal ogive and logistic models; cognitive component models; rating scale model; nominal response model; and many more. There are at least 50 IRT models in the measurement literature (see, for example, van der Linden & Hambleton, 1997).

MODEL FIT AND IRT SOFTWARE

Details on item and ability parameter estimation can be found in Embretson and Reise (2000) and Hambleton, Swaminathan, and Rogers (1991). As for IRT software, Assessment Systems Corporation has provided a great service to the measurement profession by collecting books and software from many of the publishers and making them available through their own catalogue (see www.assess.com). In addition, they publish the MicroCAT System and IRT parameter estimation software (e.g. ASCAL, RASCAL). Some of the Rasch model and its extensions software (e.g. FACETS and BIGSTEP) can be obtained from MESA at the University of Chicago. Other publishers of software include Scientific Software (e.g. MULTILOG, PARSCALE) and Computer Adaptive Technologies (CAT), Inc.

Figure 3 shows an example of how model fit at the item level can be addressed. The item characteristic curve is estimated and assumed to be correct. For intervals along the ability continuum (denoted 1, 2, 3, 4, 5, 6 and 7 in the figure) the actual item performance of examinees in each interval is calculated. A comparison is made between the actual item

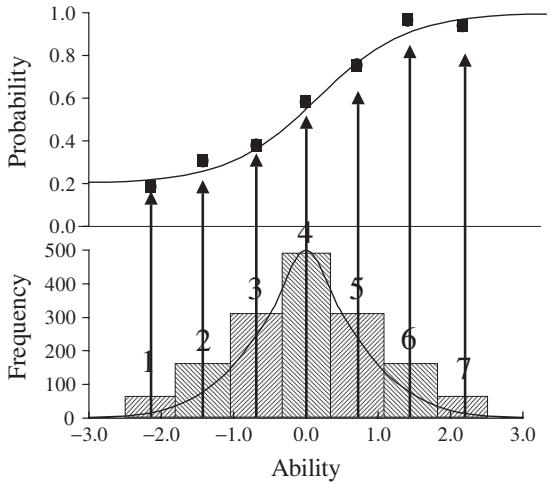

Figure 3. Assessing model fit.

performance and the predictions assuming the model to be true, and when the differences between actual item performance and predictions assuming the model to be true are small, as they are in Figure 3, the model is considered to fit the available data. Normally, what is desired in these model fit studies are differences (called 'item residuals') to be small and randomly distributed around the ICC. Of course the process must be repeated for each item, and there are many other analyses that are often carried out to investigate model fit including studies to assess the assumption of unidimensionality, and checks on item and ability parameter invariance. Statistical tests are also available.

FUTURE PERSPECTIVES AND CONCLUSIONS

Presently, item response models, especially the one- and three-parameter logistic models for analysing 0–1 data, are receiving increasing use from testing agencies. Other models not discussed here are models for handling polytomous response data and multidimensional data (see, for example, van der Linden & Hambleton, 1997). Measurement specialists are also exploring the uses of IRT in preparing computerized banks of test questions and in computer-administered and computer-adaptive tests.

The various applications have been sufficiently successful that researchers in the IRT field have shifted their attention from a consideration of IRT model advantages and disadvantages in relation to classical test theory to consideration of such IRT technical problems as goodness-of-fit investigations, model selection, parameter estimation, and steps for carrying out particular applications. Certainly some issues and technical problems remain to be solved in the IRT field, but it would seem that item response model technology is more than adequate at this time to serve a variety of uses in the testing field. Useful introductory references include Embretson and Reise (2000), Hambleton, Swaminathan, and Rogers (1991) and Wright and Stone (1979). For more advanced material, Hambleton and Swaminathan (1985) and van der Linden and Hambleton (1997) may be suitable.

JOB CHARACTERISTICS

Motivation and achievement at work is an interactive phenomenon it results from the intricate interplay between characteristics of the job and characteristics of the person. The nature of job characteristics, though, is changing at a much faster pace than personality variables. Job changes are related to changing organizational designs and structures, caused by environmental pressures, such as the increased globalization, rapid technological changes and tougher competition. The increased reliance on autonomous but temporary teams leaves fewer clearly defined job positions. Consequently, the area of research on job characteristics has become more challenging than ever. There is a strong need for conceptualizing dimensions of job characteristics which are universal and stable in a period of transition, filled with both a lot of uncertainty and arising opportunities.

INTRODUCTION

Two broad orientations and theoretical preconceptions may be distinguished when describing job characteristics. The first orientation is job-oriented and yields information about job outputs, guidelines, job contexts and tasks. Examples for this approach, which are provided in the section about tests, are the *Job Diagnostic Survey* (JDS), and *Functional Job Analysis* (FJA). The second orientation is worker oriented and yields information about aptitudes, abilities, critical incidents, behaviours and personality traits needed for succeeding in a particular job. Examples given in the section about tests are the *Position Analysis Questionnaire* (PAQ), the *Holland Position Classification Inventory* (PCI) and critical incident techniques like *Behavioural Expectation Scales* (BES).

Both approaches are complementary. Thus, job-oriented information can be used for drawing inferences about worker characteristics, and worker-oriented information can be used for gaining insights about jobs. The former has been demonstrated by Gottfredson (1997): job complexity is increasing with technological change and globalization. It follows, that intelligence or general mental abilities must be increasingly critical for success, which is indeed the case. The latter has been illustrated by the work of Holland (1997). His theory began with a worker-oriented, personality test approach, but over the years has moved toward an ecological, job-oriented perspective. Gottfredson and Holland (1996) classified all occupations in the *Dictionary of Occupational Titles*, which is based on FJA, in terms of a personality typology. Thus, jobs may also be described as 'personality niches' that elicit, develop and reward basic patterns of interests, competencies and behaviours (Gottfredson & Richards, 1999).

JOB CHARACTERISTICS IN A CHANGING ECONOMY

Jobs are the building blocks of organizations (Ghorpade, 1988). If organizations have to change, job characteristics must also change. In fact, technological changes and globalization tend to affect jobs first, which consequently become the building blocks of organizational change (see Figure 1).

In times of rapid changes, the following questions arise: what will change in job requirements? Can new performance patterns be foreseen or already perceived? Which job characteristic dimensions will be or will remain useful? The differentiation of job-oriented and worker-oriented approaches will be of heuristic value to gain some answers to these questions.

A Worker-Oriented Approach to Job Characteristics

Holland's theory (1997) provides a parallel way of describing people and environments since environmental profiles are characterized in ways analogous to personality profiles. The six environmental models are described in Table 1.

It is predicted that occupations will reflect particular patterns of job characteristics and rewards depending on which of the Holland environmental models they most resemble. It is further predicted that workers will be attracted to environments which closely match their personality. Thus, people are motivated to create congruence between their personality type and their working environment. It should be mentioned, however, that job choices are often also based on choices by significant others, driven by market forces, risk considerations, and are by no means so deliberate and conscious as the Holland model suggests.

Will the Holland model provide a useful description of a job characteristics dimension as well as the interaction of person and environment in the future? It can be expected that one of the most pervasive influences of technological innovations and globalization on job characteristics from a worker-oriented perspective may be sketched as follows: jobs will be less consistent

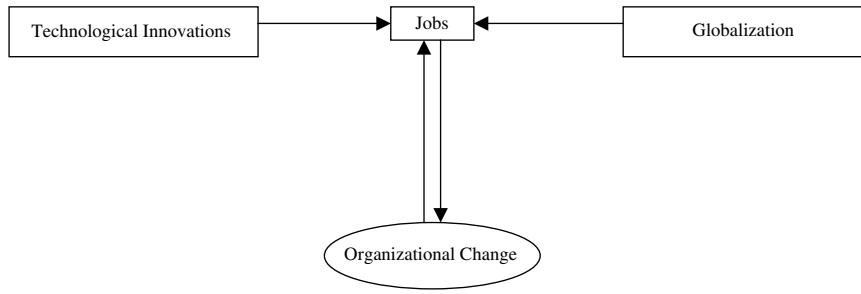

Figure 1. Jobs as building blocks of change.

Table 1. The six environmental models in Holland's theory (see Holland, 1997: 43–48)

Environment	Demands, values and competencies
Realistic	Using machines and tools; technical competencies; rewards people for having traditional values
Investigative	Symbolic, systematic, and creative investigations; scientific and mathematical competencies; rewards people to be complex, abstract and independent
Artistic	Create art forms or products; creativity; rewards people for enjoying ambiguous, free, unsystemized activities
Social	Inform, train, develop, cure others; empathy; rewards people for seeing the world in flexible ways
Enterprising	Selling or leading others; dominance and speaking abilities; rewards people for striving for power and status
Conventional	Ordered and systematic manipulation of data; clerical competencies; rewards people for being dependable and conformist

and differentiated in terms of the personality types they demand. Thus, job environments will represent more diverse demands and rewards, and the gap between the highest and lowest of the six job aspects described in Table 1 will decrease.

This is illustrated by the increased reliance on autonomous but temporary teams and fewer clearly defined job positions in the new economy. For example, many jobs today are organized around the 'cross-functional team' where technicians, computer experts, scientists, marketing specialists and human resource managers closely work together to create new business solutions. Consequently, no single type as described in Table 1 suffices to describe all demands, values and competencies needed in a 'cross-functional team'. Thus, jobs in the new economy will probably be more undifferentiated and thus less narrow concerning the involved personality traits than traditional jobs. They will stimulate and afford a wider range of behaviours, beliefs, and competencies on the one hand, but also provide more ambiguous guidance (Weinert, 2001). In an extreme case, a 'cross-functional team' may demand and reward all six Holland environments at close points in time and may actually ask for all six personality types. Nevertheless, differentiation will remain a valid job characteristics dimension. Undifferentiated job environments which demand, for example, Artistic, Enterprising, and Investigative competencies at neighbouring points in time will be a challenge both for job-analysis as well as for personnel selection.

Job environments in the new economy may function like a melting pot for diverse personality traits and behaviours in organizations. This is unlikely, though, for another trait – intelligence. Already in the past the major distinction among jobs has been their general intellectual complexity level (Gottfredson, 1997). This is shown by factor analysis of job analysis data revealing that the first factor obtained is the mental complexity of the work required from workers to perform. For example, attributes loading highly on this factor are the PAQ factors *using various information sources*, and *communicating judgements*. Also high-level information-processing activities according to FJA – like compiling, planning, reasoning and decision making – are highly correlated with patterns of intelligence. There is strong evidence that technological change as well as globalization both make jobs increasingly intelligence-loaded. Jobs become more and more enriched by content-diverse mental tasks involving learning, problem solving, and information processing, which is the essence of intelligence.

> *Where the old industrial economy rewarded mass production of standardized products for large markets, the new post-industrial economy rewards the timely customization and delivery of high-quality, convenient products for increasingly specialized markets. Where the old economy broke work in to narrow, routinized, and closely supervised tasks, the new economy increasingly requires workers to work in cross-functional teams, gather information, make decisions, and undertake diverse, changing, and challenging sets of tasks in a fast-changing and dynamic global market.* (Gottfredson, 1997: 121)

From a worker oriented view of job analysis, thus, general mental ability as a highly general information-processing capacity has been one of the most critical personality characteristics for being successful in a wide range of jobs, and will be increasingly so. Over the decades, strong evidence has accumulated that there appear to be minimum IQ patterns that increase steadily with job level and rise constantly with time. It can be expected that jobs will uniformly demand higher general mental ability on the one hand and more diverse social competencies, traits, and values on the other hand.

A Job-Oriented Approach to Job Characteristics

A job-oriented approach is devoted to the content of jobs. An example is the research concerning the Job Characteristic Model (JCM) of Hackman and Oldham (1976, 1980). This job design theory identifies five core job characteristics: task identity, task significance, skill variety, feedback from the job and from agents and autonomy. According to Hackman and Oldham, these job characteristics give rise to three psychological states (feelings of meaningfulness of the work, knowledge of results achieved and responsibility for one's own work outcomes) which in turn affect personal work outcomes of the job incumbent like general satisfaction and internal motivation. Thus, the JCM is devoted to the motivational capacity of a job.

All five job characteristics can be combined to create an index of overall job complexity, and as

has been argued above, technological innovations as well as globalization increases complexity of jobs. Advanced manufacturing technology makes it possible for workers to produce large parts of or even whole products (task identity), and often demands cross-functional manufacturing solutions (skill variety). Skill variety is also increased since people will often not remain in one job or area of speciality for a long period of time (Weinert, 2001). 'Boundaryless' career principles like protean careers and career ownership will result in greater autonomy in the job. 'High involvement work teams' coordinate schedule, and distribute the work on their own, giving the individual a large amount of responsibility and independence. Tougher competition between organizations for talented employees results in more feedback from agents, as is indicated by the increasing use of '360-Degree-Feedbacks' in many organizations. It seems like an open question, though, if changing organizational designs and structures as reaction to increasingly specialized markets will also lead to more task significance.

While the five core job characteristics identified by JCM are clearly of relevance also in the new economy, it has been criticized because of its limitation for advanced manufacturing technology. Jackson et al. (1993) have proposed a set of other job characteristics as significant determinants of employee well-being and performance which are listed in Table 2.

Another important job characteristic is production uncertainty which may be defined as the degree to which a qualified incumbent faces unexpected problems in the course of job performance (Wright & Cordery, 1999). As mentioned above, contemporary work systems are increasingly characterized by instability and unpredictability. Uncertainty should receive explicit treatment as a variable within job analysis since it may moderate the impact of other job characteristics on personal work outcomes. For example, affective well-being seems to decline under more traditional job designs as uncertainty increases, but seems to increase under empowered job designs (Wright & Cordery, 1999).

The JCM may also be criticized because of its individualistic bias. Cross-cultural research suggests that social interdependence is an attribute with significant motivating potential especially in collectivistic cultures (Marcus & Kitayama, 1991). Job attributes which effect a response of experiencing responsibility for the work of others are increasingly important also in countries with an individualistic background, but have yet received too little attention. Van der Vegt et al. (1998) distinguished between initiated task interdependence, received task interdependence, and outcome interdependence, and report substantial and combined effects of the three social interdependence dimensions on personal work outcomes of individual team members. Note that the three social interdependence dimensions affect personal work outcomes via *responsibility of others work*, a variable originally not included in the JCM.

In sum, the JCM will remain at the core of interest of job analysis. It should be supplemented, though, by job characteristics which reflect ongoing technological change (like problem-solving demand) and globalization (outcome interdependence).

TESTS

The function of job analysis is to clarify job responsibilities, to develop selection systems and to identify training needs. A large array of instruments is available today to meet these functions. Table 3 provides a brief overview over some frequently used tests and procedures.

Table 2. Job characteristics which are significant especially for advanced manufacturing technology (see Jackson et al., 1993)

Job characteristic	Description
Timing control	Opportunity to determine the scheduling of his or her work behaviour
Method control	Individual choice in how to carry out given tasks
Monitoring demand	The extent of passive monitoring required
Problem-solving demand	Cognitive processing required to prevent or recover errors
Production responsibility	The cost of errors in terms of lost output and damage to equipment

Table 3. Frequently used tests and procedures in job analysis and some of their advantages and disadvantages

Test/procedure	Advantages	Disadvantages
Position Analysis Questionnaire (PAQ, McCormick, Jeanneret & Mecham, 1972)	Gives an understanding of cognitive job components	Provides little information regarding the non-cognitive characteristics that are fundamental to perform
Holland Position Classification Inventory (PCI, Gottfredson & Holland, 1991)	Assigns scores to a job for each of the six Holland dimensions (Realistic, Investigative, Artistic, Social, Enterprising, and Conventional).	The six dimensions may be too broad for the definition of specific jobs
Behaviour Expectation Scales (BES, Smith & Kendall, 1963)	Offers a customized way of strategic job analysis; may have highly motivating effects on incumbents	Is time consuming; problems with transferability between different organizations or departments
Job Diagnostic Survey (JDS, Hackman & Oldham, 1975)	Offers an operationalization of the job characteristic model	May not be valid in societies and organizations with a collectivistic/interdependent background

Probably the most frequently used instrument of a worker-oriented job analysis is the PAQ (McCormick, Jeanneret & Mecham, 1972). The PAQ primarily measures information-processing demands of the worker in the job and gives us an understanding of cognitive job components. It provides little information, though, regarding the non-cognitive characteristics that are fundamental to perform.

The latter is addressed more directly by the recently developed PCI (Gottfredson & Holland, 1991), which is an application of Holland's theoretical formulations in classifying jobs. The PCI is designed to assign scores to a job for each of the six Holland dimensions (Realistic, Investigative, Artistic, Social, Enterprising, and Conventional). Respondents are asked to indicate what people have to do in their job, what are the personal characteristics and skills exercised, and what personal values are expressed. Maurer and Tarulli (1997) were able to show that the PCI yields expected correlations between traditional job analysis variables and the Holland constructs. For example, *variety* and *autonomy* were positively related to the Investigative and Artistic dimensions and negatively related to the Conventional construct. De Fruyt and Mervielde (1999) demonstrated the fruitfulness of the PCI environmental typology also from the perspective of the Big Five model of personality description.

Worker-oriented approaches to describing job characteristics will remain influential, because personality characteristics like intelligence, extraversion or conscientiousness have a strong genetic component and will be important for jobs at any time in human evolution. As has been mentioned above, though, it can be expected that workers will have to exercise a wider range of personal characteristics in the new economy. The PCI could be too undifferentiated to describe most of these personal characteristics fundamental to perform in the future.

Job-oriented approaches also face a problem: we need to do job analysis for jobs which do not exist yet (Schneider & Konz, 1989). Thus, in times when new jobs can be created almost overnight many practitioners need a flexible method of designing their own strategic job analysis. Behavioural Expectation Scales provide this flexibility since they are developed through an iterative procedure that results in scaled expectations of independent performance behaviours.

This technique, which involves three distinct steps, has been first reported by Smith and Kendall (1963). In the first step, behavioural episodes or critical incidents are generated which illustrate job performance dimensions. This first phase has been proven to be an excellent way of worker-oriented job analysis, especially if many organizational perspectives (managers, peers, subordinates, clients) are involved in the process of defining and clarifying success-critical behaviours for the job. The first phase of constructing BES is a meaningful job analysis for incumbents because they uniquely

understand the jargon and situations used in the content of behavioural anchors. It also holds a high motivational potential, since it may be considered as an 'empowered' form of job analysis in the eyes of subordinates.

Also, the second and third phase may be considered as part of a job analysis. In the second step, the behavioural incidents are retranslated into performance dimensions. Incidents are retained only if they are reliably placed in the dimension for which they were generated. Needless to say all three phases are done by different people (around 10 per step). The third phase scales each remaining incident according to the level of performance it represents. In this last step, different perspectives between superiors and subordinates arise reflecting different perceptions of the job. However, only those incidents make up the final BES where inter-rater-agreement is at least 80% in the second and third step. This procedure results in worker-oriented job scales with excellent reliability and very high face validity and, thus, a common 'reference system' for all incumbents. A very advantageous side effect of BES is the motivation superiors and subordinates gain by constructing this common 'reference system'.

Another future-oriented job analysis process is an instrument based on the JCM (Hackman & Oldham, 1975). The JDS is designed to assess the motivational capacity of jobs. It contains items measuring the extent to which workers feel the characteristics are present in their job and statements about job characteristics on which workers must agree or disagree. There is considerable evidence that variations in the job characteristics measured by the JDS exert an influence on people's feelings and motivation at work. Job significance (the combined effect of task identity, task significance and skill variety) is positively correlated with meaningfulness of work. Feedback positively influences knowledge of results. Autonomy is positively associated with responsibility for own work (Van der Vegt et al., 1998). These job characteristics are also positively correlated with empowerment conceptualized as a gestalt of autonomy, competence, meaningfulness and impact (Gagné et al., 1997). Wright and Cordery (1999) showed that job characteristics leading to higher job control may positively influence intrinsic motivation and job satisfaction only under conditions of high production uncertainty.

Functional job analysis (FJA) has been in the forefront of analysing job characteristics since the 1930s. It will remain influential since it is based on a very simple theory: FJA systems are based on the notion that job situations call for some involvement on the part of the worker with data, people and things which are expressed through sets of common functions or activities. FJA currently consists of three systems: The Department of Labour system, Sydney Fine's Functional Job Analysis and the Job Information Matrix Systems (Ghorpade, 1988). All job analyses consist of defining functions of the job and placing them within the hierarchy of complexity. Figure 2 shows the hierarchy of worker functions in the Job Information Matrix Systems with the most complex function at the top and the least complex at the bottom.

FUTURE PERSPECTIVES

The area of research on job characteristics has become more challenging than ever in a rapidly changing economy. We often do job analysis for jobs which do not exist yet. This forces practitioners to conceptualize dimensions of job characteristics which are universal and stable, and which consequently hold the promise to be relevant also in the future. A worker-oriented job analysis seems to be adequate since personality variables are highly stable and will clarify job responsibilities also in the future. It has been noted, though, that there is no well-researched method for identifying personality characteristics for *specific* jobs. The Big-Five approach as well as the Holland types must be considered as too general to be linked to valid personality predictors of specific job performance. Five to six personality factors are sufficient only to define *job families*. In the future, we need to define job characteristics in terms of more specific personality descriptions as provided, for example, by the CPI.

There also is a strong need for more research on the universality and stability of job-oriented dimensions of job characteristics. For example, research concerning the JCM must demonstrate that the core job characteristics unfold their motivational capacity also in collectivistic societies and organizations. Since about 70% of the world's population comes from collectivistic societies this seems like a rather important question. A related topic is the following: some

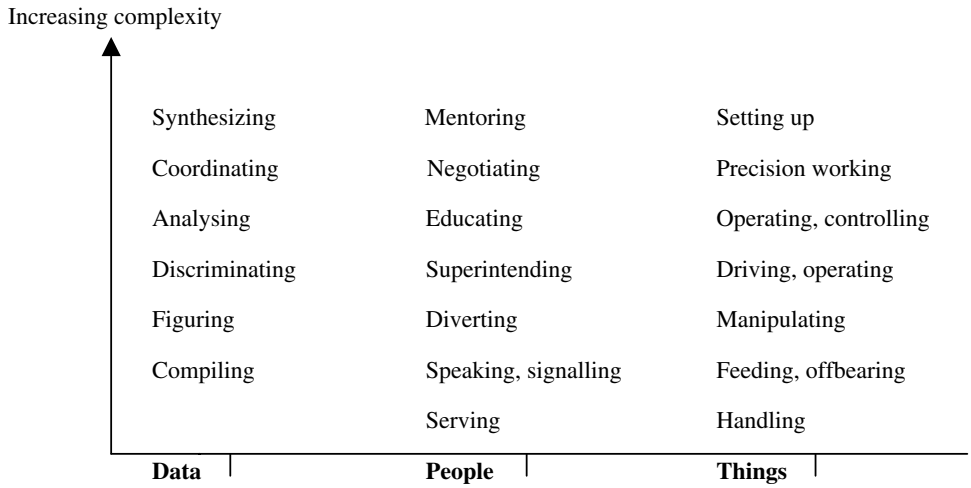

Figure 2. Worker functions (see Ghorpade, 1988: 237–254).

authors have suggested that the inclusion of non-task factors as independent variables in the JCM have important effects in many jobs which primarily consist of dealing with other people. For example, a study by Landeweerd and Boumans (1994) indicates that variables like job satisfaction, health complaints, and experienced significance of nurses can be better predicted if the JCM includes work dimensions like social-emotional leadership of the head nurse and patient attending. Since in post-industrial societies a rising percentage of jobs are in the customer service, the measurement of social relationships and interdependence as part of the job characteristics is of increasing importance.

CONCLUSIONS

Psychological job analysis will be able to prove its significance for the future if it becomes truly interdisciplinary. At a basic level, this means to fully appreciate that motivation and achievement at work is an interactive phenomena, which results from the intricate interplay between characteristics of the job and characteristics of the person. At a more general level, this also means to acknowledge influences of technological changes, globalization effects, migration and even demographic factors. Thus, research on job characteristics really seems to provide an exciting laboratory for related disciplines like psychology, sociology, business administration and job engineering.

JOB STRESS

INTRODUCTION

Job Stress Assessment (JSA) stands for methods claiming to capture stress in occupational settings. Consequently, JSA deals with phenomena occurring at work, like drop in performance and productivity, psychological and somatic complaints as well as health disorders attributed to work conditions. These phenomena are conceived as the result of a process called stress which is induced by stressors and leads to strain (stress reactions).

ASSESSMENT APPROACHES AND MODELS

Basic Common Assumptions of Stress Models

In the history of stress research (see e.g. Appley & Trumbell, 1986) some approaches focused on physiological and behavioural response patterns as stress reactions (e.g. Cannon, Mason, Selye, Levi, Frankenhaeuser, Ursin) and some identified and differentiated stressors (e.g. Dohrenwend). Others promoted the modelling of the mediating stress process between stressors and strain as an interactional or even transactional process indicating the individual coping behaviour in a given situation (Lazarus, Cox, McGrath).

There is agreement that JSA should consider all aspects mentioned below (see e.g. Cox & Griffiths, 1999; Chmiel, 2000; Schabracqu et al., 1996): characteristics of the job in relation to the individual and situational resources, mentioned as demand–resource discrepancies (stressors), the efficiency of compensatory regulation (coping), motivational patterns of conflict and negative emotions (strain) and long term effects on health (disorders).

There are two mainstreams of approaches with different topics and methods (Gaillard, 1993): the 'experimental' approach on the background of

cognitive and physiological psychology focuses on mental load, whereas the 'correlational' approach of social and health psychology concentrates on affective well-being, complaints and psychosomatic disorders. Therefore, we differentiate between mental load models corresponding with the 'experimental' approach and health models related to the 'correlational' approach.

Mental Load Models

These models are dealing with the imbalance between task demands and individual resources and the coping behaviour resulting from it. They either focus on effort-regulation (Hockey, 1997; Sanders, 1983; see Gaillard, 1993), problem solving (Hockey, 1997; Schönpflug in Appley & Trumbell, 1986) or multiple level hierarchy of regulatory control (Frese & Zapf, 1994; see Semmer in Schabracqu et al., 1996). The models differ with respect to the sort of job and personal characteristics. Sanders' cognitive energetics model considers task variables and energetic resources, while Hockey's compensatory control model, just like Schönpflug's economic approach, relates task and environmental variables to the management of effort and performance regulation. Various types of data are obtained: performance data (reaction time, errors), self-assessment data (subjective load measures) and physiological data of different systems, e.g. the cardiovascular system, the adrenocortical (cortisol) and adrenomedullar system (adrenaline, noradrenaline) and, recently, the immune system. The methods are from the same type when dealing with workload assessment (see Tattersdal in Chmiel, 2000). The action-oriented approach is methodologically somewhat different, however, describing performance patterns to fulfil task-related goals under limiting conditions (Semmer in Schabracqu et al., 1996).

Health Models

These models consider job features and their influences on job-related health (see Le Blanc et al., 2000 for the following references). They are mainly based on observational, interview and questionnaire data. According to the early Michigan Model (Kahn et al., 1964) psychological stressors develop from an imbalance between job characteristics and job expectancies which are related to individual resources. Stressors such as role conflict, role ambiguity and role overload lead to strains as precursors of psychosomatic complaints and psychosomatic diseases. Recent models assume patterns of job variables as predictably (linear, curvilinear) related to strain and mental health, e.g. the person–environment (P-E) fit model of French et al. (1982), Warr's vitamin model (1994), the job demand-control model of Karasek (1979), the demand control–support model by Johnson (1989) and the effort–reward imbalance model by Siegrist (1996).

OBJECTIVES AND MEASUREMENT INSTRUMENTS

JSA refers to the objectives listed below. Due to different mainstreams of approaches ranging from epidemiology to psychophysiology different types of instruments are deployed. For overviews (inclusively all references below) see Hurrell, Nelson and Simmons (1998), Dunckel (1999), Fahrenberg and Myrtek (2001).

Measuring Discrepancies between Demands and Resources

Measures of discrepancies between demands and resources can refer to job contents, working conditions, employment conditions or social relations at work. Within each category we can describe discrepancies between demands and resources. For instance, with regard to working conditions the following discrepancies can be described: the discrepancy between the demand at a given *time of day* and *energetic resources* (e.g. shift work, sleep deprivation, jet lag); between *time on task* and *capability of sustaining effort* (e.g. fatigue after long driving); between the *time pattern* of demand and *performing capability* (e.g. time pressure).

There are methodological aspects concerning the type of measurement which should be used:

- *Analytic–synthetic aspect*: Only feeble attempts have been made in measuring demand–resource discrepancies analytically so that measures for both, demands and resources, are considered. Instead, research is dominated by 'synthetic' job stressor

measures which get their status by means of implicit assumptions about discrepancies.

- *Objective–subjective aspect*: By means of most job stressor measures, those conditions are identified as stressful which are perceived as aversive or which even have high incidence of strain. Consequently, it is controversially discussed how measures precisely separate antecendents (stressors) from consequences (appraisal, strain) (see Kasl, 1998). Objections are raised against self-report measures especially if they focus on transactional appraisal rather than on work. It seems that the more specifically we study a job the more input is made to get objective or even analytically derived measures.
- *Demand–resource aspect*: Sometimes job stressor measures are either conceived in terms of work-demand (e.g. time pressure) or in terms of resources (e.g. temporal degree of freedom). It remains indistinct whether the same phenomenon is measured.
- *Stressor–moderator aspect*: Often job variables are categorized into stressors (e.g. time pressure) and moderators (e.g. type A personality, low social support). The distinction, however, only makes sense for testable models, e.g. when hypotheses on intermediate processes between stimulus and the final response can be studied. From a demand–resource discrepancy perspective, the moderator-variables belong to resources (individual, situational). Consequently, if there are different sources of discrepancies the pattern of those should be regarded.

Analytical Approaches

- *Laboratory job simulation studies* are suitable to identify demand–resource discrepancies analytically, e.g. the simulation of an office job (Schönpflug; see Chmiel, 2000) allows determination of the demand–resource discrepancy by measuring the number of task operations per time and the capacity of working memory under the influence of situational capacity limiting conditions (noise, negative feedback).
- *Job surveys* may be analytically designed if a theory gives criteria explicitly for the evaluation of discrepancies as models like the action theory does (TDS; Semmer in Schabracqu et al., 1996).

Observational Job Stressor Measures

Observational methods for job analyses are based on observation of job processes and interviews with job incumbents and supervisors (see Dunckel, 1998). Deployed methods are:

- PAQ – Position Analysis Questionnaire (Mecham, McCormick & Jeanneret; see Hurrell et al., 1998): stressors like repetitive work, shift work, physical discomfort, vigilant tasks, worker autonomy etc. Adaptations in non-English speaking countries, e.g. the German FAT and AET (see Dunckel, 1999), also new developments, e.g. the German TAI (see Dunckel, 1999).
- TBS – activity evaluation system (Hacker et al., 1995; see Dunckel, 1999), an instrument based on action theory: temporal and procedural degree of freedom etc. (26 scales [s]).
- ISTA – instrument for stress-related task analysis, observational version in analogy to a self-report version with the intention to apply both, objective and subjective, measures (German: see Dunckel, 1999): task complexity, task variability etc. (19s).

Self-Report Measures

Most methods are based on self-reports of employees (see review by Hurrell, Nelson & Simmons, 1998).

- SDS – Stress Diagnostic Survey (Ivancevich & Matteson, 1984): role demands, workload, time pressure, task demands, etc. (15s).
- WES – Work Environment Scale (Moos, 1981) assesses the perception of work climate: work pressure, control, task orientation, peer cohesion, etc. (10s).
- JCQ – Job Content Questionnaire (Karasek, 1985); refers to Karasek's model: psychological job demand (workload and role conflict), skill utilization, job decision latitude (3s).
- OSInv – Occupational Stress Inventory (Osipow & Davis, 1988): role overload, role insufficiency, role ambiguity, role

boundary, responsibility, physical environment (6s).
- OSInd – Occupational Stress Index (Cooper, Sloan & Williams, 1988): job and organizational characteristics (6s); revision: PMI – Pressure Management Index (Williams & Cooper, 1998).
- GJSQ – Generic Job Stress Questionnaire (Hurrell & McLaney, 1988): workload, responsibility, role demands, etc. (13s).
- JSS – Job Stress Survey (Spielberger, 1994): Severity and frequency for job pressure and organizational support (2s).
- JDS – Job Diagnostic Survey (Hackman & Oldham, 1975): feedback, task significance, task variety, task identity, interaction with coworkers, autonomy (6s).
- ISTA (see above).

Measuring Efficiency of Compensatory Regulation

The stress process develops when the applied coping strategies are inefficient in managing the discrepancies between demand and resources. Costs of performance protection may be additional regulation expenditure (effort, time, strategies), new problems and demands (e.g. not in time), changed goals, reduced aspiration levels, and negative external feedback.

Laboratory Work Simulation Studies

Well controlled experimental studies are needed to describe processes related to compensatory control and its efficiency. Examples are laboratory work simulation experiments on performance and suboptimal energetic resources and on resource management under stress (e.g. Hockey in Chmiel, 2000). Usually, the costs of compensatory control in protecting performance are studied in experimental settings by measuring the following behavioural patterns:

- *Performance measures* focus on secondary performance decrements (selective impairment of low-priority task components, neglect of subsidiary activities, attentional narrowing) and strategy changes (shift to simpler procedures).
- *Subjective and physiological measures of regulatory costs* indicate increase of effort (e.g. SWAT – subjective work load assessment; TLX – task load index: see Chmiel, 2000; heart rate variability) and fatigue (e.g. eye-lid parameters: see Backs & Boucsein, 2000).
- *Behavioural measures* relate to post-task preference for low-effort activities, risky decision making etc.

Analyses in Occupational Settings

Some of the self-report job stressor instruments include measures of coping, e.g. OSInd: coping strategies. Occasionally, self-report measures of coping strategies are obtained (e.g. in form of diaries) in field studies focusing on transactional processes. However, elaborated methods are not available. Attempts to incorporate scales of coping have not been successful due to unsufficient reliability.

Motivational Pattern of Conflict and Negative Emotions

As a consequence of inefficient coping, a motivational pattern results which is characterized through the hopelessness of reaching goals, the conflict between goals, e.g. the ambivalence to engage sufficiently in coping, a state of emotional tension and job dissatisfaction, and low competence to regulate negative emotions. Epidemiologists use questionnaires and interviews. Psychophysiologists study physiological response patterns.

Self-Report Measures

Some examples of a large variety of self-report measures follow (for a review see Hurrell et al., 1998):

- Emotional tension (tense, anxious, worried, non-calm, -relaxed, -contented)
  - STAI – State–Trait–Anxiety Inventory (Spielberger et al., 1970)
  - Index of job-related anxiety (Caplan et al., 1975) on the basis of STAI
- Fatigue (fatigued, tired, weary, non-alert, -energetic, -lively)
  - Subscale of many mood adjective check lists (e.g. ADCL by Thayer)

- Other mood aspects, like depression, anger-hostility etc.
  - Adjective check lists: POMS – Profile of mood states (McNair et al., 1971), and similar versions
- Physiological complaints
  - Symptom lists, like the GHQ and SCL (see below), CMI – Cornell Medical Index (Brodenan et al., 1949), FBL – Freiburg complaints list (see Fahrenberg & Myrtek, 2001)
- Job dissatisfaction: subscales in JCQ, ISTA.

Physiological Response Measures

Measurement procedures for the following physiological systems can be found in, e.g., Backs and Boucsein (2000) or Fahrenberg and Myrtek (2001).

- Cardiovascular activity: e.g. blood pressure, heart rate variability, emotional heart rate
- Hormonal activity: catecholamines (noradrenaline, adrenaline) in blood or urine, cortisol in serum and saliva
- Immunological indices: immunoglobulines and cytokines.

Measuring Long Term Effects on Health

Research is focused on chronic states of mental and somatic disorders. Special interest refers to the burnout syndrome: 'a state of physical, emotional and mental exhaustion caused by long term involvement in emotionally demanding situations' (Pines & Aronson, 1988). With respect to diseases emphasis has been placed on coronary heart disease. However, also diseases of other systems have been studied, e.g. the respiratory system and the gastro-intestinal system. Nowadays diseases of the immune system are of increasing interest.

Self-Report Measures

Examples of frequently used self-report measures are (for a review, see Hurrell et al., 1998):

- SCL – Symptom-Distress Checklist (Derogatis, 1977): somatization, hostility, phobic anxiety, depression, paranoid ideation, etc. (9s).
- GHQ – General Health Questionnaire (Goldberg, 1978): (4–8s).
- BM – Burnout Measure: physical, emotional and mental exhaustion (Pines & Aronson, 1988) (3s).
- MBI – Maslach Burnout Inventory (Maslach & Jackson, 1986): emotional exhaustion, depersonalization, personal accomplishment (3s).

Objective Measures

These measures include parameters of physiological response patterns (see above) and behavioural indices, like stress-related absenteeism, consumption of drugs, alcohol and nicotine.

Summary

Table 1 gives a summarized overview of typical and frequently used JSA measures mentioned above.

METHODOLOGICAL PERSPECTIVES

Combined Field and Laboratory Studies

A combination of field and laboratory studies may be an efficient methodology to improve our knowledge about job stress and the methodology of testing hypotheses. Field studies describe phenomena of a certain type of job stress and laboratory studies test the assumed interrelations between stressors and strains. Examples are provided by studies on office workers (e.g. see Schönpflug in Appley & Trumbell, 1986).

Analysis of Causal and Temporal Sequences

Experimental research is explicitly concerned with detecting causal and temporal sequences between stressors and strains. Correlational survey studies referring to the wide range between stressors and health problems often confine to causal and temporal interpretations. There are, however, testing procedures and statistical methods available which allow such

Table 1. Job stress assessment: summarized overview of measures with regard to objectives

Objectives	Measures

interpretations to be tested (e.g. Frese, 1985). As long as job stress assessment is to a large extent based upon subjective reports, causal and temporal sequence conclusions cannot be drawn unless method variance due to response sets and styles (e.g. negative affectivity bias) is tested. Analytical research designs and data analysing methods, e.g. using structural equation models, are available.

Ambulatory Monitoring as a Bridge between Surveys and Laboratory Testing

Today and even more in the future, portable equipment and enhanced methodology does and will allow objective real life assessment of job conditions as well as behavioural and physiological activity (see Fahrenberg & Myrtek, 1996, 2001). These objective measures become less expensive and difficult to obtain in comparison to the so far cheaper, more easily available and more convenient self-report measures. By means of ambulatory monitoring it is possible to study the processes at work more directly as by means of surveys. In comparison to laboratory studies they have the advantage of greater external validity. Furthermore, longitudinal studies are more feasible to design. Exactly these are needed to study the development from strain to diseases. Finally, ambulatory monitoring may bring together the two approaches, mental load and health models.

FUTURE PERSPECTIVES AND CONCLUSIONS

So far, job stress assessment comprises models and methods belonging to a wide range of approaches like epidemiology and psychophysiology, correlational and experimental methodology, micro-level and macro-level analysis. We should enhance interaction and communication between the approaches. Models and methods for job stress assessment have to be referred to a more ecological and concrete context of occupational jobs. Both will improve the more stress will be longitudinally studied as the process between demand–resource discrepancies and disorders.

LANDSCAPES AND NATURAL ENVIRONMENTS

INTRODUCTION

As commonly used in behavioural research, 'natural environment' refers to a large outdoor area with little or no apparent evidence of human presence or intervention (Pitt & Zube, 1987). In contrast, 'landscape' refers to a view over or into an area of land, or the area and landforms encompassed by a view (Daniel, 2001). Although research and practical efforts may focus on a landscape as the visual aspect of a natural environment, definitions of landscape often eschew the human exclusion criterion typically used in defining a natural environment. Landscape designations such as 'cultural', 'pastoral', and 'natural' imply varying degrees of human involvement.

In line with these definitions, most landscape assessment work treats the person as a viewer, whereas assessments concerning natural environments commonly treat people as visitors seeking an appropriate setting for outdoor recreation activities, including but not limited to viewing scenery. Work in both areas serves descriptive and evaluative purposes (Craik & Feimer, 1987). Whether relying on experts, technical devices, and/or perceptual capabilities of an appropriate panel of human observers, descriptive assessments characterize landscapes and natural/recreational settings in terms of physical or other attributes that are grounded in some conception of environmental quality, such as scenic beauty. Evaluative assessments document observer responses to landscapes or natural/recreational settings using criterion variables that reflect on an underlying conception of environmental quality, such as ratings of scenic beauty or the importance of escape from stressors. Together, descriptive and evaluative assessments can provide a basis for predicting public responses to changes in the environment.

Pressing concerns about human impacts on the possibilities for realizing valued outcomes drive much of the assessment work on landscape and natural environments. Human activities can add to scenic and other amenity values, or they can diminish or destroy them. Recent decades have seen demand for buildable land, natural resources, and infrastructure increase alongside demand for outdoor recreation. Environmental policies in many countries now direct environmental managers to weigh the demands of competing uses and users. To fulfil this responsibility, managers need information on how users experience and evaluate not only environments as they now exist, but also environmental changes associated with different management alternatives.

APPROACHES AND THEORIES

Daniel and Vining (1983; see also Daniel, 2001) overview several landscape assessment

approaches. Ecological and formal aesthetic approaches rely on biologists and other experts to classify landscapes using ecological or formal attributes as a basis for scenic quality judgements. For example, a landscape architect applying the Visual Management System (USDA, 1974) would render an area's features (e.g. rock outcroppings, lakes, streams, vegetation) in terms of form, line, colour and texture. He or she would then assign the area to one of three scenic quality categories according to the diversity of its formal attributes. When joined with other information, such as the number and type of users, the classification would support decisions about the suitability of activities that would alter the formal attributes of the landscape, such as timber cutting. Problems with expert approaches include the uncertain validity of chosen attributes as indicators of visual quality; potential disagreement by experts on landscape classifications; lack of sensitivity to variations in visual quality given broad quality categories; and lack of public input despite differences between expert and public aesthetic preferences.

In contrast, a psychophysical approach relies on public input (Daniel & Vining, 1983). For landscapes viewed on-site or with the aid of surrogates, observers provide judgements of scenic beauty, preference, naturalness or some other variable. They do so using rankings, paired comparisons, a rating scale, or some other method. The objective is to then develop a mathematical model that relates their judgements to practically meaningful physical variables on one or more scales (e.g. land use type; number of trees of a given diameter per unit area; amount of grass covered surface per unit area; presence of water features). With accurate and reliable psychophysical models comprising variables that they regularly monitor, managers can estimate visual quality impacts of environmental changes without having to survey new samples from an affected public. Relatively reliable and sensitive assessments are claimed for this public perception-based approach. Daniel and Boster's (1976) Scenic Beauty Estimation procedure is a widely used example.

Daniel and Vining (1983) associate theorizing on the visual experience of landscape with a second type of public perception-based approach to landscape assessment, the psychological. Like the psychophysical approach, the psychological approaches locate scenic quality in the meeting between person and environment, not in either alone. In contrast to the psychophysical approach, they have a basic research interest in affective, cognitive, and behavioural processes that mediate the relationship between environment and scenic beauty or preference judgements. Their utility for environmental management, however, still requires linking the psychological variables they comprise to specific physical referents.

Several theories propose that aesthetic and evaluative responses to landscapes originate in an evolved capacity to rapidly evaluate environmental conditions according to their relevance for survival. For example, Kaplan and Kaplan (1989) assert that an evolved evaluative capacity serves ongoing needs for making sense of and acquiring information from the environment. When viewing a scene, order perceived among visual elements (coherence) serves understanding, whereas their number and diversity (complexity) serve information acquisition. The visual array also enables inferences about staying oriented (legibility) and acquiring new information (mystery) when going further into the environment. In several studies guided by this theory, some participants have used rating scales to indicate how much they liked each of a sample of scenes while others have rated each scene in terms of one or more of the informational predictors (e.g. a single item for coherence: 'How well the scene ''hangs together''. How easy is it to organize and structure the scene?'). Regression analyses then treat the scenes as cases (for a review of such studies, see Kaplan & Kaplan, 1989).

North American, European and Asian samples consistently prefer scenes of natural landscapes over urban scenes (Ulrich, 1993). Although this general finding may reflect adaptedness to the (natural) environments of human evolution, theorists accept that learning processes also shape preferences, as through repeated pairing of beneficial experience with natural environments. Interweaving evolutionary with cultural and personal explanations for aesthetic responses to landscapes, various syntheses converge on the theme of the preferred natural landscape as the visual aspect of a setting for beneficial experience (e.g. Appleton, 1996).

This theme echoes in assessments for outdoor recreation management, exemplified by the

research carried out for land management agencies in the USA. Driver and Bruns (1999) describe the management of outdoor recreation areas as a production process that starts with the recreationist's desires, expectations, and preferences; proceeds through the recreationist's interactions with the (managed) environment; generates recreation opportunities; and ultimately results in psychological benefits, among other outputs. Management efforts have over time encompassed successive aspects of this process, each of which implies particular assessment needs. Activity-based management has focused on supplying opportunities to perform particular activities, but without considering the psychological dimensions of recreation opportunities or recreation quality. Experience-based management (EBM) extended the focus to the psychological experiences sought in recreation. Net benefits-based management extends EBM by encompassing the full range of recreation benefits (and costs) over a longer term. To support these management approaches, researchers have assessed motives for, satisfaction with, and benefits from recreation experiences. They have developed various measures for these purposes, such as the Experience Preference Scales (e.g. Manfredo et al., 1996). Work in this area has also considered how desired outcomes relate to environmental attributes such as level of development (e.g. Williams & Knopf, 1985), as well as the acceptability of varying numbers of other recreationists (e.g. Manning et al., 1999) and levels of human-induced change in the recreation environment (e.g. Hollenhorst & Gardner, 1994).

Reviewing a multidisciplinary array of studies on outdoor recreation motives, Knopf (1987) considers what they tell us about recreation in natural settings versus recreation activities in general. The motive studies do commonly attest to a desire to experience nature per se. Stress reduction also recurs as a potent motivation. The desire to escape stress appears to covary with crowding and other stressful conditions in recreationists' everyday environments.

As important benefits of nature recreation, stress recovery and other forms of psychological restoration will remain a concern for outdoor recreation managers. Their efforts can benefit from developing theory and research on restorative environments, which extend from studies of landscape perception and outdoor recreation. One theory views psychophysiological stress recovery as a form of change supported by natural scenes with particular stimulus properties (e.g. moderate complexity) and contents (e.g. water) (Ulrich, 1993). Attention restoration theory (Kaplan & Kaplan, 1989) attributes renewal of a depleted attentional capacity to psychological distance from routine mental contents (being away); immersion in a coherent environment of sufficient scope to sustain exploration (extent); effortless attention engaged while making sense of and exploring the environment (fascination); and congruence between personal inclinations, environment demands, and environmental supports for intended activities (compatibility). Hartig et al. (1997) have published initial measures of these four factors, but further work is needed.

These theories guide a growing number of field and laboratory studies on the restorative values of natural, urban and other environments (e.g. Hartig et al., 1991). Experiments have consistently documented relatively beneficial affective, cognitive, and/or physiological changes in natural versus urban environments following stressful or demanding experiences. However, these studies have used severely limited samples of environments.

GENERAL METHODOLOGICAL CONCERNS

Assessment involves sampling from the environment to represent variation in relevant visual or recreational attributes. Relevance has to do with what people see and use, not necessarily the full range of physical or ecological variation. In landscape assessment, sampling takes into consideration the vantage points from which observers view the landscape. As a given vantage point offers numerous views that may vary widely in their character, sampling also considers viewing direction and visual angle. Additional concerns relate to the dynamic character of the landscape; visibility, the quality of light, the presence and colour of vegetation, and other visual attributes change with the time of day, season of the year, and atmospheric conditions. Beyond such variables, Hull and Revell (1989) note that the scenes people select for viewing

vary with their purposes, the meanings they attach to landscape features, their speed of movement, their emotional state, and the presence of scenic features that command attention. Such concerns, in particular the activity pursued, also hold when assessing the recreational quality of outdoor settings.

Constraints on environmental sampling relate to the method used to present environments to the people who provide descriptive judgements or evaluative responses. Respondents may not always be available on-site, and even when they are, evaluations of future conditions present a problem. Given the costs involved in transporting people to multiple field locations or a need to represent possible changes in the environment, assessments frequently use visual surrogates or simulations to depict the environment. These represent a landscape or recreation setting in its current condition or, through the manipulation of images, how it might appear, as with different timber cutting alternatives. Presentation methods have evolved substantially, and emerging virtual reality (VR) technologies can help to reduce sampling constraints grounded in the use of static images such as photographs (Orland et al., 2001).

The validity of a given presentation method rests in part on the equivalence of an observer's response to the visual surrogate vis-à-vis the place portrayed. Although high correlations or a lack of significant differences between field and photo-based ratings have often been taken as evidence of validity, Palmer and Hoffman (2001) note reasons to question these approaches to establishing response equivalence. For example, a large correlation between ratings obtained on-site and with a surrogate indicates similarity in a pattern of responses, but not whether the absolute levels of the rated variable are the same in the two conditions.

FUTURE PERSPECTIVES AND CONCLUSIONS

Population will continue to increase in the coming years, and with it competition between commodity and non-commodity uses of landscapes and natural environments. This will drive further demand for information on the visual and recreational values of landscapes and natural environments. Improved environmental sampling and representation methods will aid the acquisition and application of such information. In the broadest sense, assessments concerning landscapes and natural environments will continue to play a role in sociocultural evolution by informing decisions that weigh multiple demands placed on the natural environment (Craik & Feimer, 1987).

LANGUAGE (GENERAL)

INTRODUCTION

The practice of language assessment, both in children and adult populations, has been undertaken from various perspectives, and its evolution mirrors to some extent the development of Psychology as a scientific discipline from the first decades of the twentieth century. In this regard, there are two most influential lines of thought, generally known as the *psychometric* and the *cognitive* approaches. Since there are a number of background theoretical issues concerning the nature of language as an object of scientific inquiry that have an important bearing on either approach to language assessment, we will begin by briefly addressing these theoretical issues. This will lead us to describe the main strategies used for language assessment purposes, and to review the main components or processing levels of language and the tasks that are used in adult language assessment for each component, together with the major variables that should be taken into account in the assessment process. Finally, we will review some problems, both theoretical and methodological, that assessment procedures have to face.

THEORETICAL BACKGROUND

Language is a very peculiar object of study. It is both a declarative body of knowledge possessed by adult competent speakers, and a set of procedures (or abilities) by which such knowledge is put to use in a variety of ways in linguistic activities. Furthermore, language can be viewed primarily as a means of communication among conspecifics (human language being the most developed and sophisticated code), but also as a means of representing and conveying thoughts and intentions, as a symbolic tool or device relating sound and meaning. In this regard, the psychological study of language is at least a twofold enterprise, for it must address (1) a wide array of information types and processing levels involved in understanding and speaking (which in principle can be selectively impaired); and (2) the intimate connection between the

speakers' linguistic knowledge and abilities, on the one hand, and their cognitive and communicative capacities at large, of which linguistic skills are but a subset.

The *psychometric* approach to language assessment (e.g. Burt, 1940; Carroll, 1941; Hakstian & Cattell, 1978; Thurstone, 1938; Vernon, 1950) views language as a set of performance skills that rest on a number of underlying, more or less permanent, abilities. Although this view of language seems to parallel the competence–performance distinction proposed by Chomsky (1965), it does not carry any commitment to a rule-based account of linguistic competence or an information-processing view of the cognitive operations underlying linguistic performance. Rather, it defines 'verbal' (as opposed to 'linguistic') abilities in crudely operational terms; that is, as a direct reflection of the subject's performance in a number of standardized linguistic tasks. Language, more properly called 'verbal ability', is thus seen as a factor (or number of factors) of intelligence along which subjects may show quantitative variations. Verbal intelligence is alternatively viewed as a unitary ability, or as a set of distinct factors (e.g. 'verbal comprehension', 'verbal fluency', etc.) that can be independently evaluated. From this perspective, the targets of language assessment, or the components of verbal ability, are defined by crossing the main modalities of language use (spoken vs. written language) with the major linguistic tasks (comprehension and production), rendering the four basic language skills, namely listening, speaking, reading and writing.

The *cognitive* approach to language assessment entertains an entirely different conception of linguistic abilities. Language is seen as a cognitive faculty; that is, as a set of mental processes that operate on linguistic representations by means of a system of abstract rules that are mentally represented (as declarative but largely unconscious knowledge) (Clark & Clark, 1977; Chomsky, 1957, 1965; Fodor, 1983; Fodor, Bever & Garrett, 1974; Levelt, 1989; Pinker, 1994). Basic linguistic competence is by assumption equal to all healthy adults, who can in turn differ in their processing skills. Accordingly, language assessment procedures are theory-governed: processing models in various linguistic domains or components guide the elaboration of assessment tasks and materials. These domains are individuated in terms of the kinds of linguistic information each one of them is supposed to process. The emerging picture of the language faculty consists of a set of autonomous processing components (or levels) – acoustic, phonological, lexical, syntactic, semantic – working in a coordinated fashion to perform complex linguistic tasks (e.g. word, sentence and discourse comprehension and production).

As for cross-modal differences in language processing, no particular assumption is made about the relative autonomy of processing modalities; it is claimed at most that the processes subserving language performance may be modality-specific at the periphery, due to specific input–output constraints, but are most likely to share the same central processing mechanisms. Moreover, the cognitive approach to the study of language views the language faculty as a (partially) autonomous processing device (or module) itself with regard to other cognitive abilities or faculties (e.g. visual perception, auditory perception, motor control, musical processing, etc.), though it may make use of a common pool of processing resources in terms of attention, working memory, etc.

Since both psychometric and cognitive approaches see language simultaneously as a *unitary* and a *multiple* ability, the psychological assessment of language could provide two kinds of information: (1) information about the subject's *general* capacity to communicate by means of well-formed linguistic messages, both spoken and written; and (2) detailed information of the various components of linguistic knowledge and processes involved in the performance of language tasks, either to evaluate the level of proficiency attained in each of these components, or to ascertain the nature and possible causes of language impairments.

The assessment procedures intended to measure the level of language proficiency have been mostly used in educational settings, as a tool either in the teaching of a second or foreign language, or in the diagnosis and rehabilitation of children with language development disabilities (see entry on 'Development: Language'). On the other hand, the assessment procedures employed in the diagnosis and rehabilitation of adult language impairments (see Kremin, in this volume) have normally developed from

neuropsychological studies with brain injured patients.

LANGUAGE ASSESSMENT METHODS

From a methodological standpoint, language assessment is roughly based on three different strategies: (1) the application of *standardized tests*; (2) the *analysis of samples of speech*; and (3) the use of *experimental tasks*.

Standardized tests for language assessment are sets of highly structured tasks intended to assess subjects' knowledge of various linguistic components and their ability to carry out the processes underlying the comprehension and production of spoken/written language. In a few cases, these tests were designed to assess one particular component of linguistic knowledge or modality (e.g. 'The Token Test', de Renzi & Vignolo, 1962; 'The Object and Action Naming Battery'; Druks & Masterson, 2000), whereas in most others (e.g. 'The Boston Diagnostic Aphasia Examination'; BDAE; Goodglass & Kaplan, 1972) they include subtests that address several components of language in spoken/written modalities: phonology/orthography, lexicon (including word form and word meaning), and syntax.

As Tables 1 and 2 show, a wide variety of linguistic tasks have been developed so far. A range of different variables are thought to influence subjects' performance in these tasks, according to the results from psycholinguistic research.

In many classical neuropsychological batteries, such as the BDAE, the assessment is based on a small number of tasks with a few items in each, which makes it somewhat difficult to manipulate and control the relevant variables that influence linguistic performance, and might bring incorrect generalizations about the processing capabilities or limitations of the subjects examined.[1] In contrast, neuropsychological batteries following a cognitive approach (e.g. PALPA; Kay, Lesser & Coltheart, 1992) provide different tasks and item lists for the evaluation of particular linguistic components, allowing a more detailed and controlled assessment of the subjects' preserved and impaired abilities (while demanding a careful selection of tests on the part of the examiner).[2]

Analysis of speech samples: The need to exert close control over the variables involved in language performance, together with the influence of Chomskyan linguistics on many areas of psycholinguistic research, have strongly biased the structure and contents of standardized language tests, which are mostly restricted to the assessment of phonological, lexical and morphosyntactic domains. However, the increasing interest of linguists and psychologists in pragmatics from the late 1970s has broadened the scope of psycholinguistic research to cover the comprehension and production of complex texts, discourses and conversations.

The evaluation of *text and discourse processing* is intended to provide information about the subject's ability to understand and use broader linguistic units comprising several interrelated sentences with complex and coherent meanings. The *analysis of conversation*, in turn, reveals the subject's capacity to produce and interpret relevant messages that are tuned to the listener's informational demands, to comply with the implicit rules regulating turn taking in conversational exchanges, to properly convey communicative intentions, etc. (see 'Communicative Language Abilities' in this volume).

Discourse and conversation analyses require the recording of spontaneous (or elicited) linguistic samples: narratives elicited by pictures where the examiner controls for the content and complexity of the information expressed; story-recall texts that allow the researcher to manipulate the content and linguistic complexity of stories; conversational discourse about topics with different degrees of relevance for participants, with familiar and unfamiliar partners, etc. Once the speech samples have been transcribed (or the texts are written), a host of techniques and measures can be used to describe how subjects organize and relate their ideas across sentences (see Table 3).[3]

Discourse and conversation analysis techniques have been extensively used to examine the patterns of preserved and impaired discourse behaviour in clinical populations and normal adults. These techniques provide *qualitative* information about the subjects' ability to organize their linguistic productions, thus revealing the complex relationships between language, social context and cognitive and communicative abilities. However, given the absence of normative data, the

Table 1. Tasks used in the assessment of spoken language, and relevant factors to be controlled

Components of linguistic knowledge and processing	Tasks	Relevant factors
Phonology	Phoneme discrimination (minimal pairs) Non-word repetition Phonological phrasing Judgements on rhymes	Acoustic/phonological similarity Length of sequence Phonemic context
Lexicon		
Word form	Identification of spelled words Repetition of words and non-words Word–picture matching Picture naming Identification/naming of real objects (body parts, furniture, etc.) Auditory lexical decision task	Words vs. non-words Word frequency Familiarity Imageability Abstractness Word length Grammatical class of words (open/closed) Morphology
Word meaning	Naming from definitions Synonymity judgements Semantic association/discrimination Semantic classification Generation of exemplars from categories Questions about word knowledge	Distractors (response choices) Homophones Age-of-acquisition
Syntax	Acting-out tasks Spoken sentence–pictures matching Comprehension of verbs and adjectives Comprehension of prepositions and adverbs Comprehension of arguments in sentences Elicited production of sentences Elicited production of changes in verbal inflection Sentence repetition Grammaticality judgements	Length of sentence (number of words) Grammatical structure of sentences (active/passive, empty categories, locatives, reversible/non-reversible, etc.) Type of referents (animate/inanimate, abstract/concrete, etc.) Prosodic variations Knowledge of vocabulary

interpretation of results yielded by these techniques requires the examiner to possess an extensive knowledge of the psychological processes involved in these activities, which lie at the border between language and reasoning.

Experimental tasks: A recent methodological development in the assessment of language involves the use in clinical contexts of experimental procedures originally devised for psycholinguistic research. The justifying assumption is that both normal and impaired language processes are affected by the same sorts of variables. In neurologically intact subjects, the influence of these variables can only be detected with very sensitive measures such as reaction time, whereas in impaired subjects these variables may prevent the responses altogether. Therefore, both error rates and reaction times can be taken as appropriate measures for patients with language deficits and normal unimpaired subjects alike.

Although experimental procedures are still seldom used for clinical purposes at large, there is an increasing trend to employ computer-based tasks in the presentation of stimuli and the recording of time-locked responses from patients with language impairments. One well-known example is the use of *priming techniques*, which have been extensively used in Experimental Psychology. In semantic priming studies, for

Table 2. Tasks used in the assessment of reading and writing abilities, and relevant factors to be controlled

Activity	Linguistic component	Tasks	Relevant factors*
Reading	Phonology/ Ortography Lexicon Syntax/ Semantics Discourse	Discrimination/identification of letters Matching letter names (sounds) and orthographic representation Matching allographic representations of letters and words Visual lexical decision task Reading of words Reading of non-words Matching spoken and written words (multiple choice tests) Synonymity judgements with written words Cloze tests (with/without multiple choice tests) Questions about written sentences (open questions, true/false questions, or multiple choice tests) Summarization tasks	(Only for cloze tests) Grammatical/semantic dependence (within-clause, across-clause, across-sentence, extra-textual) (Only for text comprehension tests) Discourse genre (narrative vs. expository texts) Conceptual organization of ideas in text
Writing	Phonology Lexicon Syntax Discourse	Writing letters and numbers by dictation Writing words and non-words by dictation Copy of allographs Writing spelled words Writing names from pictures Writing sentences by dictation Narrative writing (e.g. description of pictures)	Regular vs. arbitrary orthography of words (Allograph copying tasks) Common nouns vs. proper names

*Only specific factors for the visual modality are included here, that have *not* been previously listed in Table 1.

Table 3. Parameters for language assessment that can be obtained through the analysis of discourses, texts and conversations

Spoken discourse/Written texts	Cohesion devices (syntactic, lexical and semantic relations that link linguistic items across sentences) Local and global coherence of ideas Hierarchical organization of ideas and propositions Narrative/expository schemata (global macrostructure)
Conversations	Turn-taking mechanics Conversational breakdowns and repairs Pragmatic functions (directives, responses to directives, comments and representatives, expressives, requests for objects, actions and clarification, etc.) Topic manipulation

instance, subjects are presented with a target stimulus (e.g. a written word to be identified or pronounced) preceded by a semantically related prime (e.g. *doctor* immediately followed by *nurse*). In normal speakers, the prior presentation of the prime facilitates the recognition or naming of the target word. In contrast, brain injured patients and patients affected by Alzheimer-type dementia appear to be unaffected by the semantic relationship between both words,

which seems to show that there is a functional disconnection of the lexical and semantic systems in such patients.

FUTURE PERSPECTIVES AND CONCLUSIONS

The functional complexity of human language raises a host of problems and challenges for assessment. First of all, the examiner is bound to gather detailed information about a huge number of relatively autonomous linguistic components and processing systems, which are influenced by a range of different variables. This makes it advisable to combine different tasks and procedures in the evaluation of every single component. In addition, it makes it necessary to acknowledge the close connection between some linguistic processes and other non-linguistic domains of information processing in humans, which nonetheless play a prominent role in linguistic performance (e.g. conceptual knowledge, attentional and working memory resources – whose demands are sharply increased as linguistic units become more complex, etc.).

Language assessment, as well as the clinical (and theoretical) interpretation of its outcomes, must be driven by theoretical models and by the conceptual distinctions they propose. A particular case in point is the distinction between *implicit* vs. *explicit* forms of information retrieval (see 'Memory (General)' in this volume). The observation that jargon aphasics are incapable of making semantic similarity judgements (an *explicit* task) while showing semantic priming effects (an *implicit* task) may serve as an illustration of the need to find out whether the deficits shown by a patient only affect strategic/conscious language processes or also interfere in automatic/non-conscious processes.

Another problem that commonly arises when assessing language deficits is the issue of whether selective impairments should be seen as caused by a disruption of the subject's *store* of information within a specific component of the language system (e.g. the phonological input lexicon, the semantic system), or by a trouble with *accessing* otherwise intact information within that particular component. This problem is further complicated by the fact that performance deficits can arise as a consequence of a loss of processing resources: therefore, a shrinking of the working memory span could be claimed to underlie some language impairments which were traditionally interpreted as affecting *specific* kinds of linguistic information (e.g. bound morphemes and closed-class words) in children language impairments and adult agrammatic aphasia. A useful strategy to clarify this issue involves the joint application of specific tests intended to sort out the possible underlying causes of the deficit (e.g. the use of general and language working memory tests alongside standard sentence processing measures, like sentence–picture matching).

A final question that deserves some attention is the assumption of a modular architecture for the language processing system. This can be seen both as a theoretical claim and as an empirical issue. Assessment procedures inevitably take for granted that linguistic abilities form a relatively closed set, but it is in the interest of researchers and practitioners to clarify the pattern of associations and dissociations between the different components of the language faculty, and between the language faculty as a whole and other related cognitive abilities. More importantly for assessment purposes is the need to define in a psychologically plausible fashion the nature of the internal components of the language faculty.

The traditional view that these components should be distinguished in terms of complex behavioural tasks (i.e. listening or spoken comprehension, reading, spoken production and writing) bluntly contradicts the assumptions of the cognitive view of the language system, which views the architecture of the language faculty as a set of processing devices individuated by information types (phonological processing, word recognition and selection, syntactic processing, semantic and pragmatic processing) rather than tasks or modalities. The overcoming of these theoretical differences is currently pursued by cognitive psychologists and neuropsychologists of language within the broad framework of the Cognitive Neurosciences (Gazzaniga, 1995, 2000). Undoubtedly, this new framework brings the promise of future payoffs for language assessment endeavours.

Notes

1 For instance, the auditory discrimination task in the BDAE includes only 6 words with widely different frequencies of use ('chair', 'key', 'glove', 'feather', 'chaise-longue' and 'cactus'). As Byng et al. (1990) pointed out, if a patient responds correctly to two of these items (2/6), it turns out that she will have a very defective auditory discrimination. However, the correctly identified items might be those with highest frequency names (say, 'chair' and 'key'), in which case this patient might have a normal auditory discrimination for high frequency and an impaired discrimination for medium and low frequency items.
2 In classical neuropsychological batteries, the examiner has to go through a closed catalogue of tests to be applied as a whole.
3 The analysis of speech samples can also be used to gather information about the morphosyntactic features of the subject's discourse, by examining its grammatical structure, errors, etc.

LATENT CLASS ANALYSIS

INTRODUCTION

Latent class analysis is a statistical tool for classifying objects or individuals according to their values on a set of observed, i.e. manifest, variables. Like cluster analysis, it is aimed at identifying clusters of individuals or objects that are in some sense 'similar'. In order to

separate to the terminology of cluster analysis, the groups of individuals are called 'classes' or 'latent classes' in latent class analysis (LCA) instead of clusters.

Unlike cluster analysis, the grouping is not done by means of some measure of similarity or distance between each pair of objects to be classified. There is also no need to define some criterion of cluster distance (or similarity), nor to select one of the various cluster algorithms (e.g. agglomerative, centroid method, etc.). In contrast, latent class analysis classifies objects according to their probabilities of the values of all observed variables (feature patterns of the objects). This distinction allows for two significant indications of cluster analysis or latent class analysis, respectively.

First, cluster analysis is to be preferred for small numbers of objects to be classified, LCA for large numbers of objects, say $N = 50$ or $N = 100$ be the criterion of applying one or the other. This is because in LCA the probability distributions of all manifest variables have to be parameterized (and estimated) for each latent class (which requires large numbers of observations), whereas in cluster analysis each object has to be measured according to its distance to each other object (which is more tractable for smaller sets of objects).

Second, LCA is better suited for categorical or ordinal data (where each manifest variable has a small number of values, e.g. yes–no responses or rating scale responses to some questionnaire items), whereas cluster analysis is better suited for metric variables (where some distance measure between the objects, like the Euclidean distance, is unproblematic).

But there is a third difference between cluster analysis and LCA that is significant for specifying submodels and extended models: cluster analysis is aimed at identifying a manifest classification, i.e. each object is assigned to one and only one group or cluster (which is also true for some borderline cases, that have the same distance to two or more clusters and may, therefore, be assigned to a single cluster only with high uncertainty). LCA, in contrast, assumes a latent grouping variable, so that each object belongs to each latent class with a certain (assignment) probability. This distinction may be regarded as a more academic distinction, but it has enormous practical implications. The most prominent of them is the possibilty of defining specific statistical models for each latent class. Whereas cluster analysis can only clump together objects that are more or less similar, LCA is capable of identifying classes of objects that can be described by different statistical models. Latent class analysis belongs to the family of (discrete) mixture distribution models, whereas cluster analysis does not. But before going into the details of different variants of LCA, a brief introduction to the assumptions and ideas of LCA is given.

THE MODEL AND ITS HISTORY

The concept of LCA has been developed 50 years ago by Paul Lazarsfeld (1950) who considered it as part of the more general framework of latent structure analysis. The idea of latent structure analysis was based on the distinction between manifest and latent variables. While manifest variables can be directly observed, like socioeconomic variables, item responses in a questionnaire or some codification of observed behaviour, latent variables cannot be observed or measured by means of a yardstick. The notions of a disposition, hypothetical construct, or intervening variable, incorporate the idea that theories in psychology or sociology usually are built on the basis of latent variables like intelligence or socioeconomic status, but all that can be assessed are manifest indicators like income and success or failure in an intelligence task (Lazarsfeld & Henry, 1968).

The insight that manifest variables have to be linked to latent constructs was not new at that time, since the methodology of factor analysis was well developed and often applied in various fields of research. However, there are three significant distinctions between factor analysis and the ideas of latent structure analysis. Factor analysis applies to metric or quantitative manifest variables, factor analysis introduces metric or quantitative latent variables (the 'factors'), and factor analysis does this on the basis of the correlations among the manifest variables, i.e. only considers the bivariate associations of the observed variables. Latent structure analysis, in contrast, has been developed on grounds of the philosophy that observable variables in sociology and psychology

usually are categorical, i.e. nominal or ordinal, that also the latent variable needs not to be metric but should be conceptualized as a categorical variable, and that it is insufficient to only consider bivariate associations when working with many manifest variables, among which interactions among three or more variables may exist.

The paradigm of latent structure analysis is the principle of local independence, which means that the observed associations of the manifest variables are caused by a latent construct or a latent variable. If this latent variable is held constant, the associations between the observed variables vanish. For example, income, level of education, and the brand of the owned car are associated in any representative sample. If it is true that the socioeconomic status can be described by three levels only, i.e. lower, middle, and upper class, then the associations between income, education, and brand of car are not given, when only persons of the same class are investigated. This is to say that the criterion of identifying latent classes is the absence of associations between the observed variables within each class.

Local independence means that all observed variables are independent for the same locus of the latent variable. It is a rather fundamental principle in statistical analysis and a powerful tool for constructing models. Latent class analysis is the basic model of this family of local independence models. It simply assumes that the probability of observing a pattern of indicators x, y, and z, given a latent class A, is the product of the probabilities of each single indicator, given that class:

$$P(x, y, z|A) = P(x|A) * P(y|A) * P(z|A)$$

The second assumption is that these classes (say A, B, and C) are mutually exclusive and have proportions in the population that sum to unity:

$$P(A) + P(B) + P(C) = 1.$$

Then, the model of latent class analysis is defined as:

$$\begin{aligned} P(x, y, z) = {} & P(A) * P(x, y, z|A) + PB) \\ & * P(x, y, z|B) + P(C) * P(x, y, z|C) \end{aligned}$$

Although the basic structure of this model seems to be rather simple, it could not be applied for a long period of time, since no algorithms for estimating its parameters were available. Only the work of Leo Goodman (1974) made an application of the model to realistic sets of data possible. Goodman's algorithm later turned out as a special case of the nowadays famous EM-algorithm described by Dempster, Laird and Rubin (1977). Today, some excellent software products are available for estimating the model parameters and applying the model to large sets of data (e.g. WINMIRA, Davier, 2000; LATENT GOLD, Vermunt & Magidson, 2000; the GIBBS-sampler, Hoijtink & Molenaar, 1997; PANMARK, van de Pol, Langeheine & de Jong, 1996).

These software products cover many more models than the simple basic model of LCA as described before. WINMIRA is specialized to so-called mixed Rasch models, i.e. latent class models where the Rasch model (Rasch, 1960, 1980 [2nd ed.]) holds within each latent class, but with different item difficulty parameters between the classes (Rost, 1990, 1991, 1996). Another feature of WINMIRA are latent class models for ordinal data (Rost, 1988a and b). Other programs have their own advantages and some very powerful LCA programs exist that are not commercially distributed but have to be requested from the authors (Linear Logistic LCA, Formann, 1992a and b; or LAT, Haberman, 1979).

APPLICATIONS IN PSYCHOLOGICAL ASSESSMENT

Although the field of possible applications in psychological assessment is by far larger than the number of applications available in the literature, its number is high enough to not be listed and commented here. A collection of different applications is provided in the book by Rost and Langeheine (1997), which is now available from the Internet (www.ipn.uni-kiel.de).

As an example for a typical latent class analysis in the field of psychological assessment, the analysis of social needs in a study of environmental behaviour is described in the following (Gresele, 2000).

Each five items for assessing the social need for affiliation, conformity, influence and approval have been constructed on the basis of existing questionnaires on social needs. Two items aimed at assessing the need for approval had to be removed due to failures of item construction. The remaining 18 items were analysed by means of LCA and revealed 4 latent classes that can be interpreted as social need types. Figure 1 shows the response profiles of the 4 types on the 18 items of the questionnaire. Since the response format was a 4-point rating scale, the ordinate of this figure ranges from 0 to 3, indicating the mean (expected) response of the types on the items of the questionnaire.

Only one profile is low on the items of affiliation, giving reason to call them the *introverts*. In fact, they have an intermediate need for conformity, the lowest need for influence, and a relative low need for approval, which fits to the interpretation of this type as the introverts. This class (no. 4) covers 21 per cent of the students.

The profile of class one (27%) shows lowest values on the approval items, i.e. these students are independent of approval or *self-determined*. These students have intermediate needs for conformity and influence (which underlines their self-determination) but are high on the affiliation items.

High on influence but low on conformity is the profile of the *leader* type (class 2; 27%). These students are not oriented at the norm of their peer group, but they are themselves opinion leaders. Of course, they are high on affiliation and have a high need for approval, which they strive for by leading and influencing others.

As compared to the leaders, class 3 (26%) has a stronger need for conformity but a lower one for influence. Their needs for affiliation and approval are relatively high, so that this type can be identified as the *sociables*.

This example is to illustrate that the assessment of psychological variables by means of latent class analysis needs no assumption of dimensionality of the items and goes beyond the pairwise correlations of the item responses. The analysis considers the entire pattern of item responses and identifies groups of individuals that have similar response patterns in terms of response probabilities. Hence, latent class analysis can be seen as the qualitative counterpart to quantitative item response theory: it assesses latent types instead of latent traits (Langeheine & Rost, 1988).

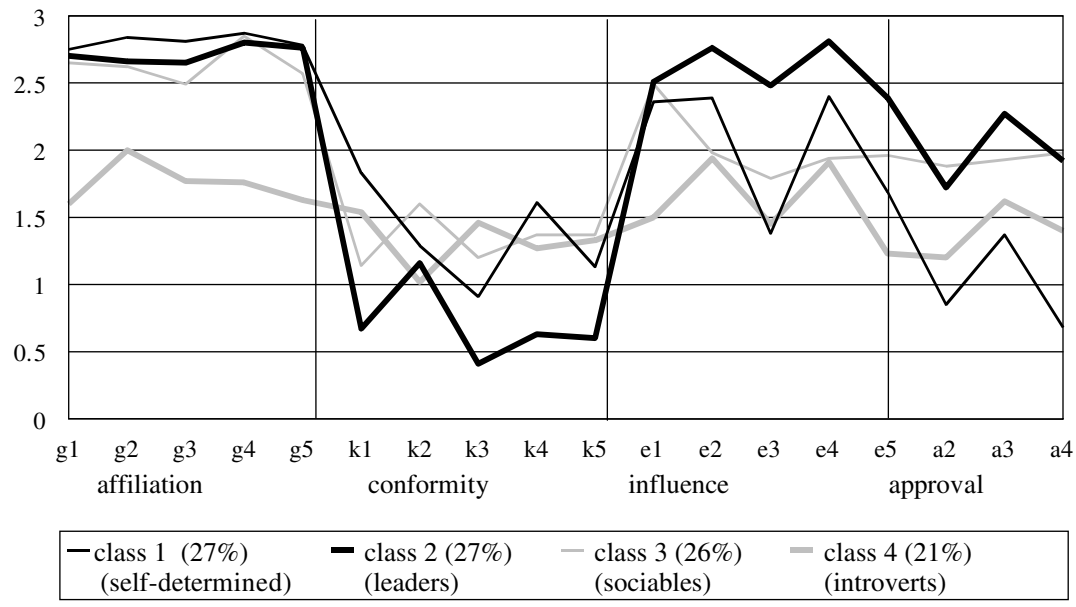

Figure 1. Social need profiles.

FUTURE PERSPECTIVES

Models based on the idea of latent class analysis constitute a growing field of methodological research. Many kinds of statistical models, like factor analysis or linear structural equation models, are going to be generalized to discrete mixture models. It certainly will become a standard for statistical data analysis to first try to unmix given data before applying some model to the entire population. The consequence for psychological assessment may be that the assessment of types of individuals will turn to be a focus of research and diagnosis, additionally to that of trait analyses.

CONCLUSIONS

Latent class analysis is only the basic model of a growing type of statistical models, that are better labelled as discrete mixture models. As a probabilistic model based on the concept of local independence, LCA parallels the models of item response theory. Moreover, latent class models may be applied when latent trait models fail to fit the data (Rost, in press).

LEADERSHIP IN ORGANIZATIONAL SETTINGS

INTRODUCTION

From an organizational standpoint one major element that sets apart successful from unsuccessful organizations is leadership, which should be dynamic and effective.

Leadership can be seen as the activity to influence others to willingly achieve specified objectives; it is clearly dependent on individual behaviours and a set of attributes which characterize a leader.

Peter F. Drucker referred to business leaders as the basic and scarcest resource of any enterprise. Therefore, it should not be a surprise that organizations are looking at the selection process for candidates (Drucker, 1954).

Trying to respond to the question of how to assess leadership at the individual level, several tools have been developed and tested during the last decades.

The entry on 'Leadership Personality' in this Encyclopedia, by Robert Hogan and Robert Tett, includes a complete summary of outside and inside assessment methods, with demonstrated validity for predicting leadership personality.

Leadership assessment at the organizational level should focus on extending the evaluation of the individual, looking at the effectiveness of the organization as a whole (Bennis & Nanus, 1985; Burns, 1978).

This entry is intended to review the concept of leadership and what attributes the followers expect from their leaders and supervisors. It will summarize the way existing tools, like Total Quality Management, are being used in the assessment process of organizational leadership.

Extending the basic traits of leadership to the entire organization, we shall cover in detail organizational leadership assessment, from a Total Quality Management standpoint (Bradford & Cohen, 1984). We shall discuss, as well, some other assessment instruments available today.

Whenever individuals attempt to affect the behaviour of other people without using a coercive form of power, we describe it as leadership. Specifically, 'leadership is an attempt at influencing the activities of followers to willingly cooperate through the communication process toward the attainment of some goal or goals' (Fleishman and Hunt, 1973).

This definition suggests that the ability to influence other people is essential to leadership and, consequently, all relationships can involve it. Besides that, communication appears to be of critical importance for this purpose.

On the other hand, the definition includes the attainment of goals. Leadership effectiveness at the individual, group or organizational level is measured by the accomplishment of one or a combination of goals.

In a hierarchically structured organization, the managers and supervisors may direct, instruct or command, but unless followers have the choice to follow or not follow, there is no leadership.

There is a clear distinction between managing and leading: the latter emphasizes 'get others to want to do' versus get others to do.

Managers get subordinates to do through objective setting and the classical management functions (planning, organizing, directing and controlling). Leaders get followers to want to do, by inspiring a vision, modelling the way, innovating, developing their people and always setting the example (see Cleveland, 1985).

LEADERSHIP CHARACTERISTICS

Much of the early work on leadership focused on identifying the traits of effective leaders. Most research was designed to identify intellectual, emotional, physical and other personal traits of successful leaders: intelligence, personality, physical characteristics or supervisory ability were investigated. In this way, a number of trait theories emerged (Gibson, Ivancevich & Donnelly, 1988).

On the other hand, the word 'charismatic' frequently comes up in discussions of leadership. For example, people might think that some leaders have charisma and other leaders don't. Leaders

don't have charisma; followers give leaders charisma. We have all seen that phenomenon with elected officials. They are often carried into office because of their charisma, but when their actions do not gain general approval, they may lose their charisma overnight. 'Charisma' has become such an overused and misused term that it is almost useless as a descriptor of leaders. Bernard Bass, professor of organizational behaviour at the State University of New York, has done extensive research on charisma (Bass, 1985).

Other people have investigated the expectations that followers have of leaders, to determine the extent to which their perceptions of leadership matched what leaders themselves said they did. One of these studies was sponsored by the American Management Association (Kouzes & Posner, 1987; Kanter, 1983).

As a result, more than 225 different values, traits and characteristics were identified, but reduced afterwards to 15 by classification. The most frequent responses, in order of mention, were (1) integrity, (2) competence and (3) leadership.

In a follow-up study, the four top characteristics of superior leaders were, by order of importance, honesty, competency, forward-looking and inspiring.

The above mentioned studies suggest the effective leadership traits which should be ideally found in leaders.

LEADERSHIP PRACTICES

Kouzes and Posner (1987) have discovered that the ordinary executives who convinced others to join them on pioneering journeys followed the path of a three-phase strategy. They refer to it as the VIP – vision–involvement–persistence – model of leadership.

Looking deeper into this dynamic VIP process, five fundamental practices were identified that enabled leaders to get extraordinary things done: (1) challenging the process, (2) inspiring a shared vision, (3) enabling others to act, (4) modelling the way and (5) encouraging the heart.

1 Challenging the process involves questioning what is done regularly in order to find new ideas and innovate. Leaders may challenge the process by searching for opportunities, experimenting and taking risks.
2 Leaders should constantly look for the future, imagining what it will be like when they have arrived at their final destinations. This activity should be shared with their people. They should envisage the future and commit others in the process.
3 Enabling others to act means leading activities to get the collaboration of the people, by building teams and empowering. They regularly foster cooperation, delegate and empower their people.
4 Modelling the way involves directing the course of action and practising what you preach. Setting the example and planning small wins are ways to model the way.
5 Encouraging the heart means recognizing and celebrating what is done successfully by the employees.

The above mentioned commitments of leadership are very deeply analysed by Kouzes and Posner (1987).

MODELLING ORGANIZATIONAL LEADERSHIP ASSESSMENT

Many models for organizational assessment have been developed. For detailed information see the entry on 'Total Quality Management' in this Encyclopedia, where several are mentioned and the EFQM (European Foundation for Quality Management) Model is analysed in detail.

A number of behavioural commitments support leadership practices. Adoption of the process of self-assessment is the EFQM's recommended strategy for improving performance (EFQM, 2000).

Self-assessment is a comprehensive, systematic and regular review of an organization's activities and results referenced against the EFQM Model. Today, many organizations are using the Model for this purpose, determining their strengths and areas subject to improvement (Peters & Austin, 1985).

Organizations carry out this cycle of evaluating and taking action repeatedly, so that they can achieve a sustained improvement. The most advanced have integrated self-assessment in the regular organization's planning cycle.

The evaluation is valid for the different criteria (enablers and results) implied in the Model. The first criterion is specifically leadership. The contribution of leadership to the business is measured by the overall results of the organization, but leadership is evaluated in terms of the specific attributes of its leaders (Kanter, 1983).

The criterion on leadership responds to the definition previously written and includes the different practices which have been covered in this entry.

The assessment reviews how the leaders demonstrate their commitment and how actively they drive improvement activities, implicating people, customers, suppliers and external organizations (Watson, 1963).

Examples of these areas are: the way they develop values and expectations and act as role models of these values; how they prioritize, fund, organize and support improvement activities within the organization; how they manage relationships with customers, suppliers and other external organizations; how they demonstrate business knowledge and get involved in education activities; how they communicate with their subordinates, listening, informing and reviewing the effectiveness of their leadership. On the other hand, how they recognize and celebrate people successes.

Being an 'enabler' criterion of the Model, leadership is assessed as a combination of the following two items.

On one hand, the approach used by the leaders in meeting their responsibilities is assessed looking at a number of attributes: has the approach a good base? Is the approach systematic? Has it preventive mechanisms? Is it reviewed against its effectiveness and changed accordingly for permanent improvement? Is it integrated in the normal business operations?

Trained assessors judge on a percentage scale how much each of those criteria are met. In this way an average percentage of performance is obtained for the leaders in the organization.

On the other hand, deployment of those attributes has to be assessed by answering the following questions: to what extent are the preceding activities extended within the organization? Do they relate with only the top of the institution or are they spread overall? Are they extended to all functions and areas of the business, or do they concentrate only in a single part of the organization?

Deployment is then assessed with another percentage, which in fact is an average of the perception the assessor has on the number of managers practising leadership at the level of the approach assessed, as opposed to the total number of executives, managers and supervisors existing in the organization.

The mean of the 'approach' and the 'deployment' is the end result of the organizational leadership assessment.

ASSESSMENT INSTRUMENTS AND TOOLS

Traditionally, interviewing techniques, group sessions and role play have been used in several ways to assess leadership capacities and potentials. Some corporations have developed direct assessment methods by asking employees by means of questionnaires what they think about their leaders.

IBM, for example, developed in the 1980s an instrument which was made available to all management levels, to assess leadership styles and behaviours by means of opinions of their employees; it was called MAP (Management Activity Profile). It helped managers to put in place improvement techniques for achieving a better leadership profile.

Assessment centre techniques, which were pioneered by Douglas Bray and his associates at the American Telephone and Telegraph Company in the mid-1950s, became very popular as evaluation techniques, in general terms, but could be used for leadership assessment purposes as well. The foundation of this technique is a series of situational exercises in which candidates for several managerial programmes take part over a certain period of time (two to three days) while being observed and rated; role playing and case analysis are part of the exercise.

However, one of the potential problems of the assessment centre evaluation procedure is that it is so pressure-packed. Outstanding employees who have contributed to the organization may simply not perform well in the centre. Another problem involves the feelings of individuals who

receive mediocre or poor evaluations. Basing promotion decisions or identification of individuals with high potential on the results of a single assessment centre experience is questionable. It may have potential benefits and potential problems.

Kouzes and Posner (1987: 309) developed a 'Leadership Practices Inventory', based on a survey. It consists of thirty-eight open-ended questions which were tested with several populations. The outcome of these procedures resulted in thirty statements (six statements for measuring each of the five leadership practices); there are two forms – self and other – which differ only in whether the behaviour described is the respondent's (self) or that of another specific person (other).

Quite a number of instruments have been developed for assessing leadership: for example, Ohio State University initiated studies in 1945, attempting to identify various dimensions of leader behaviour (Stogdill & Coons, 1957). To gather data about the behaviour of leaders, they developed the Leader Behaviour Description Questionnaire, an instrument designed to describe how leaders carry out their activities; although the major emphasis in the Ohio State leadership studies was on observed behaviour, the staff did develop the Leader Opinion Questionnaire, to gather data about the self-perceptions that leaders have about their own leadership style.

FUTURE PERSPECTIVES AND CONCLUSIONS

Organizations are using several procedures for assessing their leaders, as well as other management activities, looking at results as a consequence of 'enablers'.

The domain of the leaders is the future. Their unique legacy is creating valued institutions that survive over time.

The most significant contributions leaders may make is not to today's operational bottom-line activities but to long-term development of people and organizations who prosper and grow.

LEADERSHIP PERSONALITY

INTRODUCTION

Common sense suggests that leadership is the most important topic in the social, behavioural, and organizational sciences. A trip through the business section of any bookstore will also reveal that it is the most popular – based on the number of books written on the topic (well over 7000). The literature on leadership falls into two discrete categories. The first, and by far the largest, contains books designed for the popular or mass market. This vast literature contains nuggets of wisdom and flashes of insights from entrepreneurs, military officers, historians, business school professors, and consultants; however, it is not systematic, empirical, or verifiable, and it lacks an assessment base. In short, it is not a foundation on which to build a reliable understanding of leadership; it is entertaining rather than deeply informative.

The second literature, and by far the smaller of the two, comes from the empirical tradition of Academia. This tradition has the critically important characteristic of adhering to the standards of intellectual accountability that normally prevail in empirical research – publicly available data, standardized analytical methods, peer review, etc. By definition, then, the empirical tradition is more informative about leadership, at least in principle, than the vast collection of opinions contained in the literature designed for mass markets. But the empirical tradition suffers from four problems that limit its utility. First, it typically defines leadership in terms of the persons who happen to be in charge of the organizational unit being studied. But many, if not most, people who are in charge of organizational units attain their status for political reasons rather than because they have demonstrated significant leadership. In addition, by defining leadership operationally, the empirical tradition avoids the question of what leadership really is. Second, by defining leadership operationally, the empirical literature doesn't converge – because the characteristics of persons in charge of one organizational unit are typically different from the characteristics of persons in charge of a different unit, and it is nearly impossible to compare leadership (defined in this way) across organizations. Third, the empirical tradition has been strongly influenced by behaviourism, and as a result largely ignores the relationship between personality and leadership – from a behaviourist perspective, circumstances are more important than personality as an influence on leadership. And fourth, the empirical tradition has largely ignored the links between leadership and organizational effectiveness – arguing that effectiveness is too hard to define.

We believe that some attention to these definitional and conceptual issues will substantially clarify the assessment of leadership.

Leadership Defined

Data and common sense indicate that people are naturally selfish; nonetheless, all significant human achievement is the result of collective effort. Consequently, leadership should be defined in terms of the ability to persuade people to set aside their personal concerns and support a larger agenda – at least for a while. Leadership differs from management – subordinates respond to leaders because they want to, they respond to managers because they are paid to. Good managers, nonetheless, are often able leaders and vice versa.

Leadership and Organizational Effectiveness

All real world groups compete with other groups for desired resources – money, land, energy, food, loyal supporters, official patronage, league championships. Because leadership is a resource for a group, affecting its ability to attain its goals, leadership should be evaluated in terms of the effectiveness of the leader's team: Did it win the prize, the goal, the race, or the war?

Sometimes a good leader's team loses because it is overmatched, and sometimes a bad leader's team wins because it has superior resources; nonetheless, leadership and organizational effectiveness are co-dependent.

Leadership and Personality

To clarify the links between leadership and personality, we need first to define personality. Personality has two definitions, they are quite distinct, and they concern personality from the inside and from the outside. Personality from the inside, which we call identity, is composed of a person's values, goals, aspirations, and self-image; identity can be assessed by asking a person about his/her goals, aspirations, and self-image. Leadership assessment from the inside consists of assessing the identities of leaders and comparing them with the identities of non-leaders.

Leadership from the outside, which we call reputation, is composed of the images and evaluations of a person, as held by those people with whom that person interacts. Leadership reputation is assessed using observer ratings from whatever source a researcher might prefer. This would include assessment centre ratings and 360 feedback evaluations. Relevant research questions here include whom to ask to provide ratings, what rating dimensions should be used, and how leaders differ from non-leaders in terms of these ratings. The bottom line of this discussion is that leadership needs to be assessed from the inside and from the outside.

ASSESSING LEADERSHIP FROM THE INSIDE

As noted above, personality from the inside concerns a person's values, motives, and self-image – identity. Various methods and instruments are available to assess leadership from the inside and many of them yield valid results. For example, Sparks (1990) reports on research conducted at EXXON in the 1950s, designed to identify managerial talent. Using a combination of measures of cognitive ability, personality, biodata, and interviews, in a sample of 443 managers, and a composite success criterion (salary, level, and rated effectiveness), Sparks reports a cross-validated multiple R of 0.70. Howard and Bray (1990) report roughly comparable results using multiple methods in a longitudinal study at AT&T. Thus, it is possible to predict leadership performance using measures of identity, and in many cases with an admirable degree of validity.

The most robust procedures for assessing leadership from the inside fall into four categories: (A) projective measures of personality; (B) objective measures of personality; (C) specialized measures of personality; and (D) mixed measures of personality.

Projective Measures

McClelland (1975) and his associates have used the Thematic Apperception Test (TAT) to study leadership in a wide variety of organizations and countries. They report reasonable validity coefficients with scores for 'socialized power' (desiring power in order to bring about organizational change, not self-aggrandizement) and leadership performance.

Objective Measures

Objective measures of personality with demonstrated validity for predicting leadership fall naturally into four sub-groups. The best-known exemplars of the first group are the 16 PF (Cattell & Eber, 1961), and the Guilford–Zimmerman Temperament Survey (Guilford & Zimmerman, 1956). These inventories were constructed using internal consistency indices and factor analysis; the goal was to define reproducible factors, and predictive validity was a side issue. The second group contains objective measures of personality developed in an empirical manner and designed to maximize validity. The best-known example of this approach is the California Psychological Inventory (CPI; Gough, 1987); the well-respected CPI is widely used in management consulting around the world. The third group of measures concerns values and occupational interests. The best known of these is the Myers–Briggs Type Indicator (MBTI; McCaulley, 1990); the MBTI is not well regarded by many psychometricians, but McCaulley provides clear data that a

pattern of MBTI scores typifies executives world wide. A second important measure in this category is the Campbell Work Orientations Surveys (Campbell, 1990); Campbell shows that his inventory of values, interests, and preferences predicts a wide variety of leadership outcomes. The final category of objective personality measures contains inventories based on the Five-Factor Model (FFM; Wiggins, 1996). A substantial body of research shows that: (a) most existing measures of personality can be reconfigured in terms of the FFM, and (b) measures of normal personality based on the FFM are also robust predictors of leadership (*cf*. Hogan & Hogan, 1995). The FFM is the new paradigm for measures of normal personality, although there is strong resistance to this notion among some personality researchers (e.g. Block, 1995).

Specialized Measures of Personality

There are far too many specialized measures of personality, used to predict leadership, to cover responsibly here. There are thousands of individual scales, the best known of which concern authoritarianism, machiavellianism, self-monitoring, and dogmatism; these measures predict specific aspects of leader performance. Recent developments in theory and research suggest that these specific scales can be placed in the larger context of the FFM. Two recent special measures are important here – Emotional Intelligence (EQ) and Transformational leadership. The measurement base for the EQ movement (Goleman, 1995) is ad hoc and not well regarded by measurement experts. Nonetheless, a mounting body of evidence indicates that the ad hoc dimensions of EQ (self-awareness, self-management, social awareness, and social skill, as identified by Goleman) can be reliably measured and predict leadership performance fairly well.

The transformational leadership movement begins with Sigmund Freud and Max Weber, who argued that successful leaders have charisma, the ability to attract and develop a following. Robert House (1977) turned Weber's list of charismatic traits into a rating scale, and showed that the scale predicted leadership performance. House's results, combined with Burns' (1978) book, created a surge of interest in charismatic leadership, now termed neo-charismatic or transformational leadership, around which a substantial body of empiricism has developed, much of it based on a measure called the Multifactor Leadership Questionnaire (MLQ; Bass & Avolio, 1991). The results of this movement can be summarized in terms of six points. First, there is considerable consensus regarding the components of transformational leadership – the key components include integrity, conviction, commitment, vision, optimism, openness to new ideas, and consideration of and concern for subordinates. Transformational leadership is contrasted with transactional leadership, which emphasizes goals, accountability, performance management, and compensation. Second, these characteristics – which are desired by subordinates regardless of cultural context – resemble the components of EQ. Third, transformational leadership as a gestalt suggests that: (a) there is a moral component to leadership; (b) leadership depends on the ability to develop a relationship with subordinates; and (c) there is one best way to behave as a leader. Fourth, considerable data support these claims. Fifth, transformational leadership (and EQ) is clearly related to personality. Consequently, sixth, transformational leadership seems to be a syndrome of normal personality and should be captured by components of the FFM.

Mixed Measures of Personality

Several leadership assessment procedures combine measures of leadership from the inside with measures of leadership from the outside, and form a bridge to the next section of this entry. The two best known and thoroughly validated of these mixed measures are the Managerial Practices Survey (MPQ; Yukl, Wall & Lepsinger, 1990), and the Leadership Practices Inventory (Posner & Kouzes, 1990). The MPQ is better regarded by academic researchers; it asks a manager to evaluate him/herself in terms of 11 categories of managerial behaviour; then subordinates evaluate the manager using the same categories. The Leadership Practices Inventory is based on a critical incidents survey of experienced managers ('What did you do when you were at your best?'); the dimensions of this

assessment line up with the model of transformational leadership discussed in the preceding subsection.

ASSESSING LEADERSHIP FROM THE OUTSIDE

Subjective ratings of others' reputation as leaders began the 1950s using: (a) on-the-job behavioural description; and (b) assessment centres. Researchers at Ohio State University analysed 1800 behavioural descriptors and developed the Leader Behaviour Description Questionnaire (LBDQ; Stogdill & Coons, 1957) and the Supervisory Behaviour Description Questionnaire (SBDQ; Fleishman, 1957) which contained two broad dimensions: Consideration and Initiating Structure. Researchers at the University of Michigan created scales of leader Support, Goal Emphasis, Work Facilitation, and Interaction Facilitation (Bowers & Seashore, 1966). More recent on-the-job leadership rating scales are psychometrically improved, broader in scope, and use multiple rating sources. For example, *The Profilor* (Hezlett, Ronnkvist, Holt & Hazucha, 1997) assesses 38 managerial and leadership competencies using multisource ratings. A growing number of 360-degree measures of leader and managerial behaviour are available for use in developmental feedback (London & Smither, 1995).

The second major source of leadership ratings from the outside is the assessment centre. Originally developed in World War II to select officers and spies (Murray & Mackinnon, 1946), modern assessment centres use job simulations (e.g. in-basket exercise, leaderless group discussion) to evaluate leadership potential. The advantage of assessment centres over on-the-job ratings include control of situational factors and better assessor training and accountability. Assessment centres are valid predictors of leadership (Gaugler, Rosenthal, Thornton & Bentson, 1987), but there are many questions about what they measure (e.g. Bycio, Alvares & Hahn, 1987; Sackett & Dreher, 1982). Specifically, measures of such themes as planning and organizing, and interpersonal skills, correlate higher within exercises than individually between exercises. Nonetheless, assessment centres are a major source of data on leader and managerial behaviour.

FUTURE PERSPECTIVES AND CONCLUSIONS

Leadership assessment is intimately linked to leadership research. Key findings include the following.

Leadership is multidimensional. Leadership has often been conceptualized in terms of dichotomies; for example, Consideration and Initiating Structure, participative and autocratic styles, and person- and task-orientation. But leadership is a more nuanced concept, composed of an array of narrower facets. More specific leadership assessment allows (a) greater precision in developmental feedback and matching people to jobs; (b) richer conceptual frameworks for comparing alternative leadership perspectives; and (c) stronger tests of nomological networks guiding validation efforts (Tett, Guterman, Bleier & Murphy, 2000). A multidimensional approach also requires lengthy testing time for high fidelity data, and poses logistic problems in multisource feedback systems (Graddick & Lane, 1998).

Leadership is an evolving construct. Leadership assessment tools may need to be updated or replaced to reflect changes in the meaning of leadership as research progresses over time.

Leadership means different things to different people. Agreement among peer, subordinate, and supervisor ratings in multisource systems is moderate at best on most dimensions (Conway & Huffcutt, 1997; Dalessio, 1998; Harris & Schaubroeck, 1988). Validation efforts need to be sensitive to the diverse and sometimes competing values others hold about a given leader's role (Butterfield & Bartol, 1977), and to differences between raters in opportunity to observe leader performance.

Leadership assessment is a cognitive process and needs to be treated as such (Brown & Lord, 2001). Person perception holds promise as a framework for studying leadership reputation (Lord, De Vader & Alliger, 1986; Mount & Scullen, 2001; Sessa, 2001). Greater attention needs to be given to the mental processes by which individuals form judgements of themselves and others as leaders (Church, 1997).

Leadership effectiveness depends on the context. Skills required in higher level leadership roles typically are different from those required

at lower levels (Silzer, 1998). Leadership succession planning requires identifying the demands expected in future leadership roles.

Leader promotion can entail an assessment paradox. Despite the greater importance of leadership at higher levels, assessing senior leaders poses unique challenges due to greater ambiguity of the leader's role, increased political use of appraisal results, and reduced accountability for not undergoing appraisal (Gioia & Longenecker, 1994; Graddick & Lane, 1998; Longenecker & Gioia, 1992).

Responsible leadership assessment requires commitment from upper management that results will be used for stated purposes. Using developmental feedback data for promotion decisions can undermine assessment goals. Special efforts are needed to ensure adherence to stated purposes and confidentiality of results (Silzer, 1998).

LEARNING DISABILITIES

INTRODUCTION

The number of individuals classified with learning disabilities (LD) has increased dramatically over the last twenty years. This is because the classification of LD is based on the context of school learning. Consequently, considerable latitude exists among psychologists in defining LD. This latitude is reflected in social/political issues as well as non-operational definitions of LD (see Swanson, 1989, for a review).

The purpose of this entry is to bring some commonality to the assessment of LD. We address this problem by providing an operational definition of LD that will be useful in diagnostic assessment. Directions for future diagnostic research are also provided.

DEFINITION

Several definitions refer to LD as reflecting a heterogeneous group of individuals with 'intrinsic' disorders that are manifested by specific difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or mathematical abilities (see Hammill, 1990, for a review). Most definitions assume that learning difficulties in such individuals are (a) *not* due to inadequate opportunity to learn, general intelligence, or to significant physical or emotional disorders, but to *basic* disorders in specific psychological processes, (b) these specific psychological processing deficits are a reflection of neurological, constitutional, and/or biological factors, and (c) there is a psychological

processing deficit that depresses only a limited aspect of academic or contextually appropriate behaviour.

Thus, to assess individuals with potential LD, efforts are made to determine: (a) normal intelligence, (b) below normal achievement in isolated academic skills, (c) below normal performance in specific psychological processes (i.e. phonological awareness, working memory) and (d) adequate opportunity to learn (documentation that optimal instruction has been presented but deficits in isolated processes remain).

ASSESSMENT ISSUES

Traditionally, the assessment of individuals with LD has been directed towards (1) isolating *specific* learning problems, (2) establishing a significant *discrepancy* between IQ and achievement, and (3) demonstrating that *responsiveness* to instruction varies from those of other handicapping conditions. The literature notes problems in each of these areas (e.g. Aaron, 1997; Fletcher et al., 1994).

Specificity

Current efforts have been made to define individuals with LD as having problems in specific *primary* academic areas (word recognition, word reading fluency, arithmetic calculation) rather than problems in high-order or more complex academic domains (e.g. reading comprehension, problem solving). Although conceptually the notion of specificity is critical to the assessment of LD (Stanovich, 1986), it has not been established that the specific psychological processes that separate individuals with potential LD are different from other individuals who suffer similar academic problems. For example, Siegel (1992) found few differences in performance between dyslexics (individuals with LD in word recognition) and low achievers on language, spelling, and memory measures.

Discrepancy

Poor performance in individuals with LD in specific academic areas is unexpected based on their average intelligence. Identification of this unexpected outcome has relied primarily on uncovering a discrepancy between achievement and intellectual ability. These discrepancies are quantified using: (a) mathematical formulas that emphasize current achievement, IQ, or mental age; (b) standard score discrepancies; and/or (c) regression formulas that account for the effects of scores regressing toward the mean (e.g. Kavale & Forness, 1994). A discrepancy of at least 1 standard deviation in one academic domain when compared to IQ is considered by some to reflect LD.

Unfortunately, several statistical flaws are inherent in many discrepancy formulas (e.g. Reynolds, 1981). For example, the regression formulas, in many cases, are dependent on the types of tests used. In other words, it is plausible that a student could be given a different battery of tests resulting in a different classification decision using the same formula but with different tests.

Responsiveness

Efforts are made by psychologists to distinguish individuals with LD from other general handicapping conditions, such as mental retardation, visual, and hearing impairments. Further specification is made that bilingual, socioeconomic status, and conventional instructional opportunity do not adequately account for depressed achievement scores. Such specification allows one to infer that the learning problems are intrinsic to the individual. Unfortunately, traditional assessment procedures seldom provide information that assesses the stability and/or durability of these intrinsic psychological processing deficits under instructional conditions. If an individual with LD has an inability to remember specific aspects of language (phonological information), then documentation must be provided when they have been systematically exposed to such instruction.

Some literature suggests that LD individuals are less responsive to intervention than individuals with similar primary academic levels but without LD (Swanson & Hoskyn, 1998, 1999) and these academic problems persist into adulthood (e.g. Bruck, 1992). However, differential responsiveness to instruction has not been directly tested under well-controlled experimental conditions.

CLASSIFICATION RESEARCH

The implicit assumption for using discrepancy scores in the classification of LD is that individuals who experience reading, writing and/or maths difficulties, unaccompanied by a low IQ, are distinct in cognitive processing from slow or low achievers. This assumption is equivocal.

A plethora of studies have compared children with discrepancies between IQ and reading with non-discrepancy defined poor achievers (i.e. children whose IQ scores are in the same low range as their reading scores) and found that these groups are more similar in processing difficulties than different (e.g. Shaywitz et al., 1992; Stanovich & Siegel, 1994). As a result, some researchers have advocated abandoning the concept of discrepancy between IQ and achievement measures. In the area of reading deficits, some have even suggested dropping the requirement of average intelligence, in favour of a view where children with reading problems are best conceptualized as existing at the extreme end of a continuum from poor to good readers (e.g. Stanovich & Siegel, 1994). In addition, some researchers have argued that IQ is irrelevant to the definition of reading disabilities and that poor readers share similar cognitive deficits, irrespective of general cognitive abilities (Siegel, 1992).

In a major synthesis of the literature, Hoskyn and Swanson (2000) calculated effect sizes across studies to determine if LD readers and low achievers (LA) share common cognitive deficits. The characteristics of the sample are shown in Table 1. The most common standardized measures of intelligence were from the Wechsler Intelligence Tests (75% of the studies) and the most common measures of word recognition were from the Wide Range Achievement Test or the Woodcock Reading Mastery Test (57% of the studies). Table 2 shows the comparisons between the groups. Positive effect sizes favour children with LD in reading (reading disabled – RD). Effect sizes around 0.80 are considered substantial, those around 0.60 are moderate, and those below 0.20 are marginal.

Table 1. Age and psychometric characteristics of children with RD and low achievers (LA)

Variable	RD group mean	RD group SD	LA group mean	LA group SD
Age	111.05	33.34	110.92	33.48
Word recognition	79.82	5.75	84.09	5.72
Verbal intelligence	99.46	4.79	83.64	4.91

SD = standard deviation.

Table 2. Magnitude of effect size by category of dependent measure

Category of dependent measure	K	Mean effect size	SD
Phonological processing			
Speech-related phonological processing	34	0.27	0.5
Pseudo-word reading	18	0.29	0.39
Real-word phonetic analysis	26	−0.02	0.52
Automaticity (Naming speed)	55	0.05	0.45
Spelling	8	0.19	0.43
Memory	59	0.12	0.89
Syntactical knowledge	11	0.87	0.24
Lexical knowledge	17	0.55	0.63
Visual spatial reasoning			
Visual-motor skills	9	0.15	0.8
Spatial ability	37	0.36	0.67

K = number of studies.

The important results were that although the RD and LA groups share deficits in phonological processing and automaticity (naming speed), the RD group's performance was superior to the LA group on measures of syntactical knowledge, lexical knowledge, and spatial ability. Another important finding was that cognitive difference between the two ability groups becomes less ostensible after age 12.

BEST OPERATIONAL DEFINITION TO DATE

The majority of classification research in the last 10 years has focused on primary deficits in reading or mathematics. This research defines LD as those individuals with IQ scores equal to or above a Full Scale IQ score of 85 and reading subtest scores equal to or below the 16th percentile and/or arithmetic subtest score equal to or below the 16th percentile. The most commonly used intelligence tests are the Wechsler measures, and achievement tests include measures of word recognition or identification (i.e. Wide Range Achievement Test, Woodcock Reading Mastery Test, Kaufman Test of Educational Achievement, Peabody Individual Test) and arithmetic calculation (all the aforementioned tests that include arithmetic measures and the Key Math Test). This definition captures two high incidence disorders within LD: reading (word recognition), and arithmetic (computation, written work).

DIRECTIONS FOR FUTURE RESEARCH

Because the validity of defining LD is undermined by the use of discrepancy classification procedures, further research is necessary to classify such individuals. Several means of advancing the classification literature are as follows:

Choose Measures of Construct Integrity

Although current assessments use the WISC III (or WISC-R) and standardized achievement (e.g. reading) tests to determine discrepancy scores, this is not an argument for conceptual integrity (also see Kavale & Forness, 1994: 41, for a discussion of this issue). Neither a theoretical rationale nor empirical evidence is available to substantiate the claim that IQ tests, e.g. WISC III, capture the construct of 'potential'. Quite simply, it is not the case that individuals with comparable IQ scores on the WISC III have the same potential. In addition, a difference between an intelligence score on the Wechsler test and a serious performance deficit on the Wide Range Achievement Test (or any other achievement test) in the area of reading is not a valid test of a discrepancy model. Neither test fits into a theoretical framework of intelligence nor reading. Advances in testing LD are better served if classification is grounded in theory.

Ensure Independence among Measures

Discrepancy scores (or discrepancy defined groups) are correlated with their component parts, and therefore the discrepancy measure will relate significantly to other variables correlated with the component parts (Cronbach & Furby, 1970). When discrepancy scores are correlated with their component parts, there is a greater than chance tendency for them to be correlated with other variables which are associated with those component parts.

An example of the above rule is as follows. When (a) reading recognition is part of the discrepancy score, and (b) when low reading ability groups are comparable on reading recognition performance, then performance is comparable between discrepancy and non-discrepancy groups on processes (phonological awareness) related to reading. Thus, the discrepancy group is little more than a surrogate of the poor reading group. This circularity in findings has been recognized in the literature for some time (Cronbach & Gleser, 1953).

Direction of Outcomes must be Consequential in Performance

For example, *Child A* who has a high reading score, but low intelligence score, should reflect a different 'set of' or 'level of' processes when compared to *Child B* who has a high IQ score but low reading score. If individuals are

identified by use of a discrepancy, assessment must address or determine if direction is consequential on cognitive performance. If the direction is unimportant, those measures used to determine a discrepancy should be removed from the discrepancy formula.

Measures Related to Discrepancy Scores are Only Valid if Assessed on Something above and beyond their Components and Correlates

Most researchers recognize the reliability problems with discrepancy scores, but few recognize that the use of discrepancy scores implies that it accomplishes something beyond their component parts. Responsiveness to instruction seems to be a missing test in the majority studies comparing discrepancy and non-discrepancy groups. There is some suggestive research based on meta-analysis that groups with discrepancies are less responsive to general interventions than those whose IQ and reading scores are at the same low level (Swanson & Hoskyn, 1999).

FUTURE PERSPECTIVES AND CONCLUSIONS

This entry has reviewed some of the common assumptions related to definitions of LD. We also review evidence on the validity of classifications based on a discrepancy between IQ and achievement. Future approaches to defining LD will rely on cut-off scores on standardized measures above a certain criterion of general intelligence measures (e.g. standard score > 85) and cut-off scores below a certain criterion (standard score < 85) on primary academic domains (e.g. reading and mathematics). Table 3 provides a list of some common standardized measures used to assess learning disabilities.

Table 3. Some standardized measures used to diagnose learning disabilities

I	*Intelligence*
	A Wechsler tests (e.g. WISC-III)
	B Raven progressive matrices test
II	*Achievement*
	A Woodcock reading mastery test
	B Wide range achievement test
	C Woodcock psychoeducational inventory (Achievement Clusters)
	D Test of written language
III	*Cognitive processes*
	A Comprehensive test of phonological processing
	B Test of word reading efficiency
	C Swanson–cognitive processing test

LEARNING STRATEGIES

INTRODUCTION

Students differ in the approach they take to learning and in the cognitive processes they engage in when performing academic tasks, and these differences are of interest because they correlate with differences in the quality of academic outcome. The basic idea is to identify the features of more successful learning as well as the best ways to develop them. There has been much confusion and different meanings associated with the term learning strategies (LS) as well as different terms to describe similar processes.This discussion will take as a starting point the arguments of van Dijk and Kintsch (1983) regarding strategies of discourse comprehension. According to them, a strategy is 'the idea of an agent about the way to act in order to reach a goal (in the most effective way)' (p. 64), or, in other words, '... a global representation of the means of reaching (a) goal. This overall means will dominate a number of lower level, more detailed decisions and actions' (p. 65). It is not a detailed planning, since sequences of actions, complex informations and circumstances interact to produce a given result, but 'merely a global instruction for such necessary choice to be made along the path of the course of action' (p. 65). Related to strategies, and contrasted to mere actions, they describe a *move* as 'any action that is accomplished with the intention of bringing about a state of affairs that ... will (probably) lead to a desired goal' (p. 66). Thus, 'a strategy is defined as a cognitive unit dominating only the moves of an action sequence and not each action' (p. 66). It is also interesting to keep in mind that in 'complex problems part of these strategies may be consciously intended and, yet, part of them will also be more or less automatized' (p. 70). Finally, they describe a tactic as a system of strategies.

In the field of LS, two sources of differences among students can be distinguished which might be understood in the light of these concepts. A*pproaches to learning* dominate, give meaning and a style to most of the activities a student carries out; in terms of the above discussion, they might be taken as tactics students may adopt when learning. On the other hand,

strategies have to do with more discrete, yet complex activities such as the way they address an academic reading or set out to write an essay.

The goals students with opposing approaches pursue in learning differ in important ways; students with a *deep approach* try to learn and to change their perception of reality, while those with a *surface approach* try to comply with academic demands, pass exams or take learning as a means to get a better job. Approaches to learning have been documented to be related to teachers' practices (see entry on 'Instructional Strategies') and to correlate with different ways of performing academic tasks and with outcomes measured in various ways (Ramsden, 1992). They act at the intentional level and permeate lower level strategies. *Approaches to learning* have been summarized (Ramsden, 1992) as shown in Table 1.

LS have been defined as different ways of processing information (Weinstein & Mayer, 1986) and are often used coherently with the two main approaches (deep vs. surface). It is interesting to remember they are units complex enough to entail different moves and decisions and may comprise more or less automatized components but are by definition selected among other alternatives, thus flexibly and deliberately applied to reach specific goals. Weinstein and Mayer offer a taxonomy of LS which has become a classic and includes 6 categories of *cognitive strategies*, in fact 3 types of strategies carried out in basic (learning of isolated facts) or complex (learning of integrated bodies of knowledge) tasks. These strategies are: *Repetition*, *Elaboration* and *Organization*. These cognitive strategies are complemented by 2 categories of support strategies: *affective* (anxiety and motivational) and *metacognitive*, having to do with planning, monitoring and reviewing.

Thus LS embrace a wide range of moves and processes from the cognitive, affective, social and metacognitive levels which interact with each other. A student with good learning strategies will be able to formulate clear task objectives, select the right cognitive activities to reach a given learning goal, learn in a self-regulated way, look out for support when needed, be able to apply the acquired knowledge to solve problems and succesfully monitor and orchestrate the whole process, thus resulting in enhanced abilities to continue learning autonomously throughout life.

ASSESSMENT METHODS

Approaches to Learning

To assess them, a number of instruments have been developed. *Interviews* with students have been used from a phenomenographic ethnographic approach, with the purpose of understanding how learning is approached and experienced (Marton, Hounsel & Entwistle, 1984). Their main difficulty is the high costs of in-depth interviews, but they are fundamental in a qualitative approach to students' experience which might then lead to more structured devices.

Various *self-report measures* have also been developed. Among the best known is the *Approaches to Study Inventory* (ASI, Entwistle & Ramsden, 1983). Its 64 items basically cover three orientations to learning (meaning, reproducing and achieving) with their corresponding

Table 1. Summary of approaches to learning

Deep approach	Surface approach
Intention to understand.	*Intention only to complete task requirements.*
Student maintains structure of task.	*Student distorts task structure.*
Focus on 'what is signified'	Focus on 'the signs'
Relate previous knowledge to new knowledge	Memorize information for assessment
Relate knowledge from different courses	Associate facts and concepts unreflectively
Relate theoretical ideas to everyday experience	Knowledge cut off from everyday reality
Relate and distinguish evidence and argument	Fail to distinguish principles from examples
Organize and structure content into a coherent whole Internal emphasis	Focus on unrelated parts of the task
	Treat the task as an external imposition
	External emphasis: demands of assessment

approaches (deep, surface, strategic) and two styles of learning (comprehension and operation) with their corresponding pathologies (globetrotting and improvidence). The *Module Experience Questionnaire* (MEQ, Ramsden, 1992) combines with scales related to teaching, deep vs. surface approaches to learning.

Learning Strategies

Self-Report: General

These self-reports consist of a list of characteristic activities students do or do not usually engage in when performing academic activities. So, they refer to what they do *generally*, not in a specific task; but it is easy to see that they can significantly change from one task or knowledge domain to another. In spite of these limitations, these procedures are an economic and quick way of assessment which can be used for screening in a first phase of work. However, they should be supplemented with more specific devices such as specific reports or observations (or both) in order to fully understand the functioning of a student.

Many of these questionnaires do not derive from an explicit theoretical framework: items have generally been selected through rational or empirical approaches, but often the overall theoretical framework is not made explicit. Thus the number of scales and items widely differ and it is often difficult to compare them. Among those with best foundations we shall mention (Zimmerman & Palmer, 1988).

The *Learning and Study Strategies Inventory* (LASSI, Weinstein et al., 1988) includes 77 items distributed in 10 scales: Attitude, Motivation, Time Management, Anxiety, Concentration, Information Processing, Selecting Main Ideas, Study Aids, Self Testing and Test Strategies.

The *Motivated Strategies for Learning Questionaire* (MSLQ, Pintrich, Smith, García & McKeachie, 1991) is comprised of 81 items distributed in 15 scales: 6 related to aspects of motivation (Value, Expectancy and Affect) and 9 to Learning Strategies: Cognitive (Rehearsal, Elaboration, Organization and Critical Thinking), Metacognitive and Resource Management (Time and Study Environment, Effort, Peer Learning and Help-seeking).

The *Inventario De Estrategias de Aprendizaje* (IDEA, Vizcarro, Bermejo, del Castillo & Aragonés, 1996) has 153 items distributed in 14 scales (plus Sincerity): Attention, Establishing Connections, Knowledge Representation, Oral & Written Expression, Assertivity with Teacher, Motivation-Effort, Perception of Control, Non-Repetitive Learning, Taking Examinations, Work Management, Metacognition, Physical & Environmental Conditions and Reflective Learning.

Self-Report: Specific

These devices ask for the subject's report through interviews or think aloud protocols while or immediately after performing a given task (reading, problem solving, written composition, etc.). Typical *interview* questions include: 'How does a good reader go about reading?' Or 'Did you look back while reading?'

Think aloud protocols may take two forms: asking the subject to report the operations he/she is performing along a task or at specific moments (for instance, in reading, after each paragraph or at given marks in the text). These reports may also take place after completing the task, supported by audio or video recordings to stimulate recall.

Observation

This method of data collection may be used to register some open features of strategic behaviour, traces or results of behaviour. An example of the first kind is observing task centred behaviour or search for information of external sources. As traces of behaviour, underlining book or note taking are typical in situational tests of study or reading behaviour. Finally, a synthesis elaborated after reading or number of correct answers to open or closed questions are frequently used as a measure of quality of outcome of reading or studying, that is, as a criterion.

Recently, some simulations and electronic environments allow a continuous registration of the work done by a student and the paths followed when performing a task, thus making possible a detailed follow-up and analysis of the strategies used in task completion.

More informal data may take place in classroom observations of the process of academic performance. These informal observations are usually complemented by the dialogue between teacher and student whereby the goals and

reasons of a given strategy may be thoroughly explored. In fact, observation methods should be complemented by in-depth questioning regarding the reasons behind a given strategy or the extent of its use to gather a more precise picture.

FUTURE PERSPECTIVES AND CONCLUSIONS

One limitation of focusing on learning approaches or strategies is that we might forget about contextual demands, with which they are necessarily related. While there is not much discussion on the existence of different approaches and strategies which correlate with different levels of achievement, a crucial question is how to help students develop more effective ways of learning. Independent study skills programmes have been developed trying to teach broad LS which can be applied to any subject matter. However, other findings show strategies acquired in this way are difficult to generalize to new situations and effective LS can only be acquired along with specific content knowledge, that is through quality teaching in specific domains. The challenge, then, is to train teachers so that they are able to help students develop the appropriate strategies within their subject framework. A mid-way solution might be to help students acquire general LS which teachers will then develop in their own classrooms and subjects. A good definition and assessment of LS are required as well as the ability of teachers to observe and model the best strategies.

LIFE EVENTS

INTRODUCTION

Although it is long established that stress is related to ill health and psychological distress, there remains ambiguity about the dimensions of stress involved in this process, specifically the types of stressors that have more deleterious effects on health. To study the naturalistic stress process, the field requires valid and reliable measures of *life events*, to use in conjunction

with measures of vulnerability to stress. A *life events scale* is a comprehensive list of external events and situations (stressors) that are hypothesized to place demands that exceed the capacity of the average individual to adapt. Sample items in life events scales include recent divorce or separation, the death of a close family member, a job loss, moving, and the onset of a health problem.

Two types of life events assessment dominate the literature; exposure to out-of-the-ordinary events that have the capacity to change the patterns of life or arouse very unpleasant feelings (*life events*) and exposure to relatively minor, less emotionally arousing events whose effects disperse in a day or two (*hassles*). These measures often, but not always, take the *environmental* perspective on stress (e.g. Cohen, Kessler & Gordon, 1995), which tends to view events as triggers for disease. Life events measures differ to the extent to which they include self-reports of perceived stressfulness and threat posed by events (*appraisals*) and enduring or recurrent difficulties in an area of life (*chronic stressors*). The dimension of appraisal incorporates more fully the *psychological* perspective on stress (e.g. Lazarus, 1999). These variations in life event assessment have developed in response to different types of research questions, the outcome of interest in the investigation, and the period of time over which a particular event is thought to have impact, whether a few hours, or many years.

LIFE EVENTS

There are two general methods of life events assessment, checklist measures (Turner & Wheaton, 1995) and personal interview measures (Wethington, Brown & Kessler, 1995). Interview measures incorporate qualitative probes that specify the characteristics of life events theorized to produce physical or psychological stress, the severity of the occurrence (the threat), and the timing of life events in relationship to the outcome. Some checklist measures use standardized probes to assess perceived severity, appraised threat, and timing of the event. Both checklist and interview measures can assess chronic stressors as well as acute or discrete life events.

A typical checklist measure consists of a series of yes/no questions, asking participants to report if any situation like the one described has occurred over a past period of time (e.g. one month, a year). Checklist measures may rely on respondent self-report to rate event severity and threat, or may assign average ('normative') severity ratings developed by investigators. Either method results in a summary score of the estimated stressfulness of events experienced over a period of time.

Checklist measures are popular, inexpensive, and easy to administer. They also yield consistent relationships with physical health outcomes, which is a property that makes them useful for exploratory studies (Turner & Wheaton, 1995). The Social Readjustment Rating Scale (SRSS: Holmes & Rahe, 1967) is the ancestor of many checklist measures in current use. The SRSS included both positive and negative events because its developers believed that change *per se* was associated with changes in health status. Over time, checklists have moved toward including only negative or undesirable events, based on repeated findings that undesirable events are more predictive of severe health problems than positive events. Special measures have been developed for other populations, including adolescents and ageing adults (Turner & Wheaton, 1995).

Despite their popularity, checklist measures have been criticized on the grounds of reliability and validity. These criticisms include inadequate or generalized severity ratings, lack of comprehensiveness across different life domains and the experiences of special populations, and fall-off in reporting more distant rather than more recent events (Herbert & Cohen, 1996).

The early development of personal interview methods that use qualitative probes was driven by a perspective that assumes social and environmental changes (and anticipations of those changes) threatening the most strongly held *emotional commitments* are the basis of severe stress. This perspective also asserts that severe stress threatens health, rather than minor stress, distinguishing it from measures of hassles, or daily events (e.g. Lazarus & Folkman, 1984).

Interview measures are more often used if research requires one or more of the following: (1) more precise severity ratings, that are less contaminated by respondent appraisal; (2) the

relative timing of exposure and disease onset; and (3) establishing that stressors are 'independent' of respondent illness or behaviour. Promoters of interview methods also claim that they are more reliable and valid than checklist measures, although it is probably more accurate to assert that they measure different phenomena. Their expense rules them out for exploratory, low budget studies.

The purpose of the interview probing is to gather enough information to rate the objective *long-term contextual threat* or severity of situations. The rating of event severity is the major aim of personal interview methods, as the experience of a very severely threatening situation is hypothesized to pose a risk for illness. Rating the degree of severity and threat for objective situations has been documented over several decades in dictionaries available for researchers. Events may also occur because of the pre-existence of a physical or mental disorder. If that pre-existing disorder is as well the major outcome of the research study, interpretive difficulties arise. Rating routines for most personal interview measures of stressor exposure include an assessment of whether a situation is (1) known to be related to an actual disorder the respondent reports (e.g. getting fired because of drinking), or (2) hypothetically related to symptomatology (e.g. events involving interpersonal conflict). The Life Events and Difficulty Schedule (LEDS: Brown & Harris, 1978) is the best-known and best-documented interview method. Many interview measures use LEDS or LEDS-like rating schemes.

The LEDS has experienced criticism for its rating and interview methods. Wethington, Brown, and Kessler (1995) discuss these criticisms extensively. The most persistent criticism is that ratings of 'threat' include contexts many researchers would like to measure separately as modifiers of the impact of stressors on health. Specifically, there is a long-standing controversy over whether LEDS ratings of contextual threat cloud the distinction between event severity and the individual's vulnerability to a stressor (Tennant, Bebbington & Hurry, 1981).

All interview and checklist measures aim to be comprehensive across types of stressors. They vary, however, in whether they include comprehensive assessment of chronic stressors as well as discrete events. This distinction is important for investigators, because chronic stress assessment is apt to be more important for some health outcomes (e.g. physical precursors to heart disease) in comparison to others (e.g. onset of depression).

Measures of life events also differ in whether they include or exclude appraisal. Many checklist and interview measures of life events for the most part aim to exclude appraisal from stressor exposure assessment. Those that exclude appraisal do so because of concerns that stressor appraisal may be confounded with the health and psychological outcomes that stressor exposure is hypothesized to predict (Monroe & Kelly, 1995). Indeed, researchers have speculated that some stressor appraisals are 'caused' by underlying, persistent mood disturbance, rather than vice-versa (Stone, Kessler & Haythornthwaite, 1991).

HASSLES

Early hassles assessment relied on diary methods of collection, where respondents were asked to keep records of small events occurring over a given period of time, usually a 24-hour or 1-week period. Researchers have taken two approaches to measurement: open-ended questions which asked respondents to describe bothersome events of the day; and structured questions, simple yes or no response questions modelled on life events checklists (Eckenrode & Bolger, 1995).

Current hassle scales share the strengths and weaknesses of related approaches to the assessment of major life events and chronic stressors. One of the most persistent has been that diary methods of data collection, relying on written self-report, confound objective events with psychological appraisal processes (Eckenrode & Bolger, 1995). Hassle measures assume participants respond to the questions in a relatively neutral and uniform way (Schwartz & Stone, 1993). A second persistent criticism is that the self-report of hassles is confounded with coping. The argument here is that when a respondent copes successfully with small hassles, such as overloads or interruptions, he or she is less likely to either (1) remember the occurrence, or (2) interpret the situation as a stressor (Aspinwall & Taylor, 1997).

A third criticism is that methods of data collection for hassles are too time-consuming and expensive to use in large-scale surveys of the population, particularly on a daily basis. Most

research on daily events has been conducted in small, discrete, relatively homogeneous samples (Stone et al., 1991; Eckenrode & Bolger, 1995). Such samples limit the generalizability of findings. Almeida and colleagues (Almeida, Wethington & Kessler, 2002) have recently completed a national study of hassles, developing a telephone interview measure of hassles. Future work on life events and hassles assessment will lead to more refinements in assessment.

LOCUS OF CONTROL

INTRODUCTION

Locus of control (LOC) is an individual's expectancy about the typical source (locus) of reinforcement. Does reinforcement originate within an individual ('When something good happens to me, it is because I worked for it') or from outside ('I have no influence on what the

government does')? In the former case, we have an *internal* LOC, whereas in the latter case, we have an *external* LOC.

I provide a brief overview of the LOC construct and how it has been measured with self-report questionnaires. This task is daunting. LOC has been one of the most frequently investigated individual differences, and LOC measures have been used in thousands of empirical investigations. I have relied here on several earlier and more extensive reviews (Lefcourt, 1991; MacDonald, 1973).

In addition to its own popularity, the LOC construct has inspired related lines of research into generalized expectancies about the sources of good and bad events – notions like explanatory style, helplessness, hope, illusory control, John Henryism, secondary control, self-efficacy, and so on (Peterson, 1999). Those who work within these other traditions may not always cite LOC as the intellectual parent of their constructs, or they may insist that their own approaches are distinct. Regardless, there is considerable overlap – theoretically and empirically – between LOC and its offspring.

SOCIAL LEARNING THEORY AND LOCUS OF CONTROL RESEARCH

Rotter (1954) introduced locus of control in his social learning theory to make sense of people's varying reactions to success and failure. A radical learning theory, one that does not look within an individual to explain behaviour, would predict that success (reinforcement) should always result in continued responses, whereas failure (punishment or extinction) should never do so. This prediction proves to be wrong. In some cases, success does not produce perseverance, and in other cases, failure does not produce passivity.

Rotter therefore proposed that people's behaviour is influenced not just by reinforcement or punishment but also by their expectancies about the link between responses and outcomes. It is only when expectancies are congruent with what happens that success and failure have effects. People who do not expect that efforts and actions produce reinforcement will not have their response tendencies changed by occasional reward. And those who do expect that efforts and actions produce reinforcement will not be dissuaded from future responding by occasional lack of reward.

According to Rotter (1966), expectancies about a given situation are shaped by the features of that situation and by experiences in similar situations. These experiences accumulate and produce generalized expectancies. So, LOC is abstracted from past experiences, but it also determines future learning and thus can have a life of its own. LOC is psychologically interesting because it is *not* always redundant with reality.

Lefcourt (1991: 415) summarized what early researchers learned about the correlates of LOC:

> An internal locus of control was associated with a more active pursuit of valued goals, as would be manifested in social action ... information seeking ... alertness ... autonomous decision making ... and a sense of well-being. Those who were assumed to have a more external locus of control were often found to be depressed ... anxious ... and less able to cope with stressful life experiences.

These findings are consistent with the role assigned to LOC in social learning theory. However, other findings seemed contrary. Either LOC was not associated with the active pursuit of goals, or the magnitudes of correlations were surprisingly low.

In response, Rotter (1975) wrote a cautionary article about 'misconceptions and misuses' of the LOC construct. First, he urged researchers to take into account the reinforcement value of goals. Those with an internal locus of control may not participate in a political protest, for example, if they do not agree with the cause.

Second, he reminded researchers that LOC refers to *generalized* expectancies, and it should not be surprising that LOC plays a small role in explaining behaviour in situations in which specific expectancies are well-established. For instance, an internal LOC predicts good grades early in a student's academic career but less so as the student learns what is involved in doing well.

A third point made by Rotter (1975) is that researchers may inadvertently fall into a 'good guy–bad guy' way of thinking about LOC, assuming that internals only do good things and that externals only do bad things. So, 'internals should be more liberal, more socially skilled, better adjusted, more efficient' (p. 60). There is no reason to make these assumptions, and if they are used as hypotheses, they will not yield consistently confirming data. To have

'good' consequences, an individual's LOC must be congruent with the causal texture of given situations, and there are settings in which a realistic external LOC is more useful than an unrealistic internal LOC.

Rotter (1975) also touched upon two methodological issues that have guided subsequent researchers as they developed additional LOC measures. The first issue concerns domain-specific LOC measures. Consistent with social learning theory, expectancies about a given sphere of activity – such as academics – should better predict behaviour in that domain than expectancies about other spheres. Accordingly, recent years have seen the development of dozens of domain-specific LOC measures.

The second issue is the dimensionality of LOC. Rotter's (1966) original LOC measure, described in the next section, conceptualized the construct as unidimensional, an assumption apparently supported by factor analyses. However, Rotter (1975) pointed out that such findings are not incompatible with the possibility that there are subtypes of internality or externality and that there may be good reasons to identify these. Subsequent researchers have thus unpacked LOC.

Table 1. Representative LOC measures

IE Locus of Control Scale (Rotter, 1966)
Purpose: to measure general LOC Format: 23 forced-choice items Internal consistency: $\alpha = 0.70$ Test–retest reliability: $r = 0.50$–0.70 Validity evidence: see text
IAR Questionnaire (Crandall et al., 1965)
Purpose: to measure LOC of children in academic domains, separately for success and failure format: 34 forced-choice items, half for success and half for failure Internal consistencies: $\alpha = 0.55$ for subscales, 0.70 overall Test–retest reliability: $r = 0.70$ Validity evidence: internality scores predict grades, achievement test scores, and amount of time spent pursuing 'intellectual' activities
IPC Scales (Levenson, 1981)
Purpose: to measure internal, powerful others, and chance LOC Format: 24 Likert 6-point scale items, 8 items per subscale Internal consistencies: $\alpha = 0.60$–0.90 for subscales Test–retest reliability: $r = 0.60$–0.80 Validity evidence: subscales show differential correlates with types of political activism, types of psychopathology, length of internment among prisoners, and retrospective reports of parental behaviour

REPRESENTATIVE MEASURES OF LOCUS OF CONTROL

Space does not permit discussion of all extant LOC measures, or even a listing of them by name. My strategy is to focus on three representative measures (see Table 1).

Rotter's (1966) own *IE* (Internal–External) *Locus of Control Scale* was one of the first measures of LOC and is still widely used. It presents respondents with pairs of statements, one exemplifying internal LOC and the other external LOC. Respondents choose one statement in each pair, and the number of external choices is ascertained. The content of the items ranges widely. In the process of scale development, candidate items were discarded if they were linked to social desirability. Factor analyses implied that the resulting scale was unidimensional. Subsequent studies, however, cast doubt on both the independence of the measure from social desirability and its unidimensionality. Indices of internal consistency and test–retest reliability are nonetheless satisfactory. Validity has been established in a variety of ways, including known-groups' strategies. Individuals who arguably have an external LOC because of the circumstances of their lives – such as prisoners – score toward the external end of the scale.

Crandall, Katkovsky, and Crandall's (1965) *IAR* (Intellectual Achievement Responsibility) *Questionnaire* was one of the first domain-specific measures. The IAR Questionnaire measures LOC with respect to academic outcomes and is suitable for grade school and high school students. Like Rotter's measure, the IAR Questionnaire uses a forced-choice format. However, it distinguishes between success experiences and failure experiences. Another feature of the IAR Questionnaire is that it renders externality in terms of 'other people' as opposed to chance or fate. The IAR Questionnaire is consistent and reliable, and it has accrued good validity evidence.

Among a number of multidimensional LOC measures, Levenson's (1981) *IPC* (Internality, Powerful Others, and Chance) *Scales* have become particularly well-known. This measure distinguishes two types of externality: the belief that powerful others control reinforcement and the belief that chance is the locus of control. Three subscales therefore comprise the measure. Each is measured with statements presented in a Likert format. Levenson (1981) reported factor analyses supporting the independence of these three factors, although appreciate that these subscales are not orthogonal. Internality is negatively correlated with both externality subscales, which in turn are positively correlated with one another. Again, this measure is consistent, reliable, and valid.

FUTURE PERSPECTIVES

Several lines of current research seem fruitful. The first are studies of domain-specific LOC that investigate generalized expectancies with respect to health (e.g. Wallston, Wallston, Kaplan & Maides, 1976) and religiosity (e.g. Jackson & Coursey, 1988). Next are studies that investigate LOC cross-culturally. In light of arguments that personal control is a culture-bound construct, such investigations are important because they suggest boundary conditions to LOC as typically construed as well as discover additional expectancies that influence behaviour (Weisz, Rothbaum & Blackburn, 1984). A third line of work attempts to discern the developmental precursors of LOC and may lead to interventions that cultivate appropriate expectancies. Finally, the links between LOC and its numerous cognates deserve not only theoretical speculation but also earnest empirical inquiry.

CONCLUSIONS

LOC has long been a central topic of investigation by psychologists and will continue to be. LOC researchers have not always followed the good advice offered by Rotter (1975) about the meaning and measurement of LOC, and contemporary investigators who study cognates of LOC have certainly not heeded the analogous advice vis-à-vis their own constructs. The most important conclusion that I can offer is to echo Rotter's admonition that researchers should keep theory in mind as they design and interpret studies.

MEMORY (GENERAL)

INTRODUCTION

By a simple definition, memory is the capability of animals to acquire, retain, and make use of knowledge and skills. Since the early 1980s, the way that cognitive scientists think about memory has dramatically changed. Today, memory is more often viewed not as a unitary entity but as comprising different components or systems. Neurocognitive research has indicated that it is more appropriate to consider the human memory as a collection of multiple but closely interacting systems than as a single and indivisible complex entity (e.g. Tulving, 1985a; Squire, 1992; see also Schacter & Tulving, 1994a, for current perspectives). Different memory systems differ from one another in terms of the nature of representations they handle, the rules of their operations, and their neural substrates (e.g. Tulving, 1984; Weiskrantz, 1990; Tulving & Schacter, 1992; Schacter & Tulving, 1994b; Willingham, 1997).

Various classificatory schemes of human memory have been proposed so far. Undoubtedly, the two most influential and extended classifications are those postulated by Squire (1992) and Schacter and Tulving (1994a). Squire distinguishes two long-term memory systems: declarative and non-declarative (or procedural) memory; whereas Schacter and Tulving identify five major systems: procedural memory, perceptual representation system, semantic memory, short-term working memory and episodic memory. Related distinctions include explicit versus implicit memory, direct versus indirect memory, and memory with awareness versus memory without awareness. However, these latter dichotomies may not be memory systems, but rather forms of expression of memory. According to the Schacter and Tulving classification, retrieval operations in the procedural, perceptual representation and semantic systems are implicit, whereas in the working memory and episodic memory they are explicit. On the other hand, Squire considers declarative memory as an explicit system, whereas non-declarative memory is viewed as a heterogeneous collection of implicit abilities (Squire & Knowlton, 2000).

EXPLICIT AND IMPLICIT MEMORY

Compelling evidence for the existence of multiple memory systems is provided by experimental findings of numerous convergent dissociations (functional, developmental, pharmacological, neuropsychological, neuroanatomical) between tasks of *explicit and implicit* memory (for reviews, see Schacter, 1987; Ruiz-Vargas, 1993; Nyberg & Tulving, 1996; Schacter, Wagner & Buckner, 2000). The original distinction between explicit and implicit memory was made by Graf and Schacter (1985). *Explicit memory* is revealed by intentional or conscious recollection of specific previous information, as expressed on traditional tests of free recall, cued recall and recognition. *Implicit memory* is revealed by a facilitation or change of performance on tests that do not require

intentional or conscious recollection, such as perceptual identification, word stem completion, lexical decision, identification of fragmented pictures, mirror drawing, and so on.

Consider these two experimental situations: (1) A list of 20 familiar words is presented to subjects who are instructed to pay attention to each word because, after the presentation, they will be asked to reproduce as many of the presented words as possible. (2) A list of 20 familiar words is also presented to subjects who are instructed to perform an orienting task (e.g. pleasantness ratings). After this study phase, the subjects will be asked to say the first word that comes to mind in response to a series of three-letter word stems. Obviously, some word stems can be completed with presented words, and some cannot. The first experimental situation reflects one of the ways in which psychologists have traditionally measured human memory: by assessing deliberate or *explicit memory* of subjects for items studied in a specific learning episode with a recall test. In the second situation, it is often observed that subjects show an enhanced tendency to complete word stems corresponding to studied words in comparison to 'new' word stems. This phenomenon is known as *repetition priming* or *perceptual priming*.[1] Priming does not involve intentional or explicit recollection of the study episode, and thus it is assumed to reflect *implicit memory* for previously acquired information.

Distinction between explicit and implicit memory has had a profound impact on contemporary research and theorizing of human memory. The finding that some products of memory are expressed with conscious awareness of the previous experience, and other ones without conscious awareness of the source of the information, has constituted 'a revolution in the way that we measure and interpret the influence of past events on current experience and behaviour' (Richardson-Klavehn & Bjork, 1988: 475–476). Therefore, both experimenters and clinicians should take into account this distinction whenever they assess human memory.

MEMORY ASSESSMENT

The German philosopher Hermann Ebbinghaus (1850–1909) was the first to demonstrate that memory can be measured. His main contribution was methodological in nature. Among his most important contributions were the *study/test paradigm* for the study of memory, the basic foundation of any memory experiment and test, and *the savings method*, currently considered as an implicit memory test, which were a couple of inventions of very large influence. Since then, memory assessment has undergone an extraordinary quantitative and qualitative advance. Both the evolution and the accumulation of new memory tasks have defined the progress throughout the last century. The Ebbinghausian measure of serial recall led to new forms of testing recall (free recall, cued recall), and these measures fuelled new theoretical developments in the 1980s. Today, two major classes of memory measures are distinguished: tests of explicit memory and tests of implicit memory.

Tests of Explicit Memory

Explicit memory tests are those in which the instructions in the test phase make explicit reference to an episode or experience in the subject's personal history. Thus, they require intentional or conscious recollection of previous information. Traditionally, these tests have been considered as *the only* memory tests. Table 1 provides a relatively extensive list of tests of explicit memory currently in use (see also entry on 'Memory Disorders' in this volume).

The tests of explicit memory include *free recall*, *cued recall* and *recognition* memory tasks. Prototypically, in tasks of free recall, subjects are shown a list of items (words, pictures, sentences) and are later asked to recall the items in any order that they choose. In cued recall, subjects are given explicit retrieval cues. The retrieval cues are prompts, reminders or any additional information that guides the search processes in memory (e.g. FRUITS for the to-be-recalled words 'apple', 'plum', 'grape', 'kiwi'). In free and cued recall, memory performance is assessed simply by counting the number of to-be-remembered items recalled.

An exception to the prototypical tasks outlined above is *serial recall*, in which the subject is asked to recall the items in the order of presentation, and performance is assessed by the number of items recalled in the correct sequential order. This procedure allows the assessment of memory for order or temporal memory, one kind of memory especially relevant, for instance, in language

The Subjective Memory Questionnaire (SMQ)

*See, for references, Baddeley, Wilson and Watts (1995).
**The RBMT is one of the few memory tests to have a version for children. However, recently some memory tests for use with children have been presented [e.g. *The Children's test of Nonword Repetition* (CNRep) constructed by Gathercole, Baddeley, Willis and Emslie; *The Story Recall Test* developed by Beardsworth and Bishop (see, for details, *Memory*, Volume 2, Issue 2, June 1994: special issue on 'Memory Tests and Techniques')].

perception and comprehension (see entry on 'Language (General)' in this volume). Serial recall is also used in the well-known short-term memory task called *digit span*, that has been traditionally included in tests of general intelligence such as Wechsler-batteries.

A typical *recognition* task involves presenting a list containing the to-be-remembered or *old* items (e.g. words) just as in the presentation phase of recall tasks. However, in the subsequent test phase, subjects are shown a series of words – old items mixed with *new* items or *distractors* – and they are required to decide which are the old ones.

In the last few years, much research has also been devoted to the study of the subjective states of awareness associated with recognition memory. Tulving (1985b) introduced a new methodology to distinguish 'remember' (R) and 'know' (K) responses in recognition memory tests. An R response represents recognition with conscious recollection of the item's prior occurrence; a K response represents recognition associated with feelings of familiarity in the absence of conscious recollection. Tulving proposed that these two states of awareness reflect two kinds of consciousness, autonoetic and noetic, which are respectively properties of episodic and semantic memory. The *remember/know paradigm* merits its consideration because a number of studies have demonstrated that the recollective experience of remembering is affected in different ways by many independent variables. For our purposes, its results are especially relevant to focus on different subject variables. There is now considerable evidence that age, Alzheimer's disease, amnesia, epilepsy, schizophrenia and autistic disorders have dissociative effects on R and K responding. The general finding has been that, in the conditions mentioned, 'remember' responses are selectively impaired and 'know' responses are relatively spared (see, for review, Gardiner & Richardson-Klavehn, 2000).

Finally, and with illustrative rather than exhaustive purposes, it cannot be ignored that an unlimited number of memory-judgement tasks are also explicit memory tasks. For example, judgements of presentation frequency, judgements of temporal order or recency, judgements of input modality, judgements of source/reality monitoring, feeling-of-knowing judgements, and so on.

Tests of Implicit Memory

Implicit memory tests are those in which subjects are asked to respond to test stimuli (e.g. generate a word, classify an object, perform a motor task) without making reference to prior events. The impressive experimental evidence available about

dissociations between implicit and explicit memory tasks warrants the assumption that there are fundamental differences between mnemonic information assessed by implicit and explicit memory tests. For example, numerous studies have documented across diverse tasks that amnesic patients (and other special populations) exhibit preserved mnemonic functioning when they are assessed with tests of implicit memory, and a memory severely impaired when tests of explicit memory are given. Studies with normal subjects have also shown that under some conditions (e.g. effects of alcohol, psychoactive drugs, general anaesthesia, or certain experimental manipulations) normals exhibit implicit memory for information that they cannot explicitly remember. The most important and theoretically relevant conclusion from these findings is that implicit memories are explicitly inaccessible and vice versa, because (a) different aspects of events are encoded by distinct but interacting neurocognitive systems, and (b) diverse tasks tap different memory systems. Therefore, an adequate memory assessment requires of experimenters and clinicians to make use of explicit memory tests as well as implicit memory tests.

There are many implicit memory tests currently in use, and new tests are created every year. A general classification scheme that includes most of them has been recently proposed by Toth (2000). Implicit memory tests could be roughly organized in two major categories: *verbal* and *non-verbal* tests, and each one of them in its turn into three subclasses: (1) *perceptual* tests (e.g. perceptual identification, word stem completion, degraded word naming, object/non-object decision), (2) *conceptual* tests (e.g. word association, category instance generation, object categorization, person/trait attributions), and (3) *procedural* tests (e.g. reading mirror inverted text, probability judgements, mirror drawing, motor tracking). Generally speaking, the perceptual tests challenge the perceptual representation system, the conceptual tests involve the semantic memory system, and the procedural tests tap the procedural memory system.

Assessment of Different Memory Systems

From the multiple memory systems view, memory assessment must evolve to assess every single memory system. According to the five-fold classification system proposed by Schacter and Tulving, such systems are defined and could be assessed as follows:

1. The *procedural memory system* is a behavioural action system concerned with the acquisition, retention and retrieval of motor, perceptual and cognitive skills, simple conditioning, and non-associative forms of learning. These kinds of memory are measured by tests of implicit memory, such as the pursuit rotor task, maze learning, mirror reading, artificial grammar learning, tower of Hanoi, and so on.
2. The *perceptual representation system* (PRS) encompasses various domain-specific subsystems that process and represent information about the form and structure of words and objects. The PRS is assessed with implicit memory tests, such as perceptual identification, word stem completion, homophone spelling, picture-fragment completion, object/non-object decision, possible/impossible object decision, and many others.
3. The *semantic memory system* is the system involved in the acquisition, retention and retrieval of general knowledge of the world. Therefore, the task of assessing the status of this complex and multi-faceted system seems an impressive one. This challenge could be overcome by using a multiplicity of types of tests, such as word fluency, vocabulary, word association, naming tasks (animals, objects, etc.), recognition of famous faces, category instance generation, fact generation, category verification, semantic anomaly detection, K responses in recognition tests, and so on.
4. The *working memory system* (WM) is a short-term system that makes possible the temporary maintenance and processing of information, and to manipulate that information. The WM is measured by explicit memory tests such as the Brown–Peterson task, various memory span tests (e.g. forward and backward digit span, word span, alpha span), the size of the recency effect, the release from proactive inhibition task, the Dobbs and Rule task, mental arithmetic, and others. As Craik et al. (1995) emphasize, because WM tests do not all measure the same component processes it is advisable

to assess WM by using several tests rather than one global test.

5 The *episodic memory system* is the system for personally experienced episodes. Episodic memories are assessed with tests of explicit memory for verbal and non-verbal materials, such as free recall (immediate and delayed), cued recall, recognition, R responses in recognition tests, generation task, and others. Different tasks may be used to assess autobiographical memory, considered as a subtype of episodic memory, such as recall and recognition of famous events, the Crovitz–Schiffman technique or the cueing method, etc. In clinical contexts, the Autobiographical Memory Interview (AMI) provides relevant information about the deterioration of this kind of memory in patients.

At this point, it is worth considering that remembering and the different memory systems summarized above all refer to the past. However, as everybody knows, people are also capable of remembering what they must do in the future. The former is called *retrospective memory*, and the latter, *prospective memory*. Prospective memory is defined as the timely remembering of a planned action; everyday tasks such as remembering to phone one's sister at eleven o'clock, remembering to take medication after lunching, or remembering to reply to an e-mail this evening are all significant memory acts common to everyday living. Because both observations in the real world as well as laboratory studies show that prospective memory declines with age, brain damages and progressive brain diseases, prospective memory tasks should be given whenever memory is assessed.

FUTURE PERSPECTIVES AND CONCLUSIONS

During the last decade, students of memory have witnessed a colossal progress in scientific understanding of this capacity. However, scientists have also discovered that 'the complexity of memory far exceeds anyone's imagination' (Tulving, 2000: 727). Thus, it is not unusual for the very term 'memory' to mean many things to many people and, consequently, for the concept of 'memory impairment' to be utilized in many different ways by researchers, clinicians and patients and their families. This idea has been masterly captured by Tulving (2000: 728) when he said: 'Any claim about "memory" or "memory impairment" immediately requires clarification: About which kind of memory, memory task, memory process, or memory system are we talking?'

One fundamental reason for this lack of agreement is that memory is not a monolithic entity but a collection of different systems with multiple processes which are expressed in different ways. This idea should be assumed not only by researchers but also by clinicians and neuropsychologists in order to reduce the undesirably great distance existing between experimental research and clinical assessment. Currently, most neurosychological batteries are still focused on traditional memory tests; that is, free recall, cued recall and recognition tasks. However, implicit memory tests must be included without delay into explorations of special populations such as brain-damaged individuals, patients with Alzheimer's disease and other degenerative brain diseases, the elderly, etc., who have already showed sharp dissociations between explicit and implicit memory task performances.

Fortunately, the incipient convergence between psychologists and neuropsychologists favoured by the new Cognitive Neuroscience framework (Kosslyn & Koenig, 1992; Gazzaniga, 1995) undoubtedly will result in an impressive change in the ways human memory will be assessed in the years to come.

Note

1 Perceptual priming refers to facilitation in the identification of a stimulus (word or object) as a function of a prior exposure to the same stimulus.

MEMORY DISORDERS

INTRODUCTION

Memory enters into nearly all cognition and memory dysfunction is one of the most common sequelae of neurological disorders. It seems therefore highly implausible to consider a unitary research or assessment on memory. Thirty years ago, Tulving's (1972) contribution to the organization of memory consisted of dividing long-term memory in terms of content, i.e. episodic and semantic memory. Episodic memory refers to memory for specific events within a spatial and

temporal context. Semantic memory, on the contrary, holds information that is independent of the context in which that information was learned. More recently, Tulving's view of memory as multiple systems (1995) comprises five types of memory: procedural memory, perceptual representation system, semantic memory, primary memory and episodic memory. A great deal of research indicates that even severely amnesic patients show preservation in the procedural system (conditioning, motor-skill acquisition, perceptual learning, verbal facilitation and rule learning).

A further memory construct, which had an important impact on memory research, concerns declarative/non-declarative memory (Squire, 1993). Declarative memory is defined in terms of facts and events acquired through learning and retrieved intentionally. Non-declarative memory refers (mainly but not only) to priming and skills learning. Declarative/non-declarative memory is parallel to Schacter's (1992) concept of explicit/implicit memory.

Characteristics of memory loss depend on the locus of lesion. Very broadly speaking, damage to parts of the limbic circuit (hippocampus, fornix, mamillary bodies, anterior thalamus and cingulated gyrus) affects memory performance in different ways (Mishkin, 1982). Moreover, memory deficits arising from temporal or frontal lesions have been reported, 25 years ago, as showing qualitative differences.

NEUROPSYCHOLOGICAL ASSESSMENT

The aim of the neuropsychological assessment of memory is threefold: (i) Characterization of the brain damaged patient's memory for both clinical and research purposes. (ii) Rehabilitation, whenever possible, on the bases of the results obtained in (i). (iii) Measurement of change by comparing, for instance, the patient's performance on two occasions, pre- and post-rehabilitation programme or pre- and post-neurosurgery. The present entry develops the first goal, which comprises the assessment of both memory loss and memory preservation. Moreover, within the frame of memory viewed as an ensemble of subsystems, this entry deals with the explicit contents of memory only.

Memory deficits can be *triggered by* impaired intellectual, attentional and/or motivational functioning. However, loss of memory cannot be *accounted for* diffuse deficits of cognitive capacities since patients presenting memory loss are well able to perform normally on tests of general intellectual abilities. Memory assessment is best achieved by obtaining a comprehensive cognitive profile and by interpreting the memory performance on the basis of the patient's general cognitive capacities. The neuropsychological examination should include the patient's verbal and non-verbal IQs and an estimation of the premorbid cognitive level of functioning in order to find if there is a significant difference between pre- and post-illness mental status. Besides general abilities, it is important to assess language functions, visuoperceptual and visuospatial capacities, executive functions and, particularly, attentional functions. Indeed, attentional impairments preclude any conclusions on memory deficits since explicit memory depends on the integrity of the attentional processes. To get round this difficulty in the examination of memory, the clinician may try to minimize the influence of attentional factors by selecting the tests, when feasible. A further way to circumvent this is by controlling the patient's attention. Thus, for instance, on Warrington's (1984) verbal and non-verbal Recognition Memory Tests, the patient is asked if the items shown by the examiner (words or faces) are pleasant or unpleasant. On the contrary, some other memory tests may both rely openly on intact attention, particularly during the encoding part of the task, or they may be designed to assess attention during a learning task. Finally, an adequate understanding of memory deficits would also require assessment of current levels of motivation.

MEMORY AND ATTENTION

Patients with memory deficits, even if they are severe, may perform adequately on tests of *simple attention* span, i.e. tasks that require the repetition of information, usually digit repetition, immediately after its presentation. The Digit Span subtest of the verbal scale of the WAIS-III assesses simple attention through repetition of digits forward. Visual pointing span can be assessed by the Corsi Blocks (Kaplan et al., 1991) or by spatially organized patterns as in the visual span subtest of the Wechsler Memory Scale – Revised (WMS-R; Wechsler, 1987). Patients presenting

with generalized cognitive deficits as in dementia may fail the simple attention test. Other patients showing a relatively preserved performance on verbal and/or visual span might be unable to carry out similar tests either when information becomes more complex including, for instance, increasingly longer sentences or when an interfering task is introduced as in Brown–Peterson's technique. Immediate repetition of items requires not only preserved attention but also preserved short-term memory (STM). It has been observed, albeit much less frequently than the attentional deficit, a *genuine* STM disorder, which dissociates from long-term memory performance (Warrington & Shallice, 1969). Besides the examination of simple attention and STM, evaluation of higher levels of attention and their influence on memory functions are necessary in routine assessment. Thus, a sensitive test to disorders of *directed attention* is the Stroop Test (Stroop, 1935), which measures the capacity of the individual to inhibit a response to an overriding trait by means of directing his/her attention to a minor feature. The Mental Control Tests of the WMS-R are designed to evaluate *sustained attention*. Finally, *divided attention* is measured by means of Part B of the Trail Making Test since the patient is requested to keep both the letter sequence and the number sequence in mind and to perform the task within a set time limit.

MEMORY IMPAIRMENTS

To attempt an accurate diagnostic of memory impairments and (ideally) suggest their characteristics, clinicians need valid, reliable and sensitive memory tests. The validity of tests is essential in the prediction of everyday life difficulties that the patient might encounter. Reliability with memory tests is a delicate point due to learning effects; however, for some tests at least, reliability can be achieved by means of the use of parallel versions of the test. The more sensitive the test is to memory disorders the higher the probability to detect comparatively small changes. However, sensitive memory tests are yet to be conceived.

There are two non-exclusive models of memory assessment. (i) The global performance approach yields an overall single score and seems useful when the goal of the examination is to detect memory loss with no further specifications. This model of assessment uses the same battery or batteries of tests regardless of the individual patient's memory complaints. (ii) The flexible or cognitive approach allows detecting *and* characterizing the nature of memory deficits by means of a variety of tests chosen from a pool of standardized tasks, and/or tests conceived and constructed to detect selective dissociations of memory functions within an individual patient's neuropsychological profile. In the latter case, the newly constructed tests are also given to normal controls matched to patients for age, sex, education and handedness. The cognitive approach also provides plausible ways to reflect the complexity of anatomical data. Indeed, lesions affecting different brain areas cause diverse memory deficits, which can be identified by a careful description of the patient's performance across a wide range of selected memory tests. Selection of the memory tests described in the remaining of the entry (see Table 1) was made taking into account memory processes, performance before and after the onset of the illness and the sensory modality elicited by the tests.

A recent and fruitful approach in the assessment of memory disorders consists of determining which memory process has been most affected by the lesion. Tests are carried out to find out whether a patient is impaired in learning new material,

Table 1. Examples of tests within different memory constructs

Memory process	*Test/task*
Encoding	Immediate cued recall from the G-B test
Retrieving	Free and cued recall from the G-B test
	Free and cued recall from the CVLT
System/type	*Task/question*
Anterograde/retrograde memory	
Personal semantics	Names of three people you met after/before BI (see Kopelman et al., 1990)
Autobiographical episodes	The first/last incident recalled after/before BI (see Kopelman et al., 1990)
Public events	Current famous faces/Famous faces from the past
Modality	*Test*
Verbal	Recognition memory test for words
Non-verbal	Recognition memory test for faces

that is encoding process, or in retrieving information successfully encoded. It is also necessary, in everyday clinical practice, when dealing with *acute* insult to brain structures underlying memory, to establish whether the brain accident or illness provoked disruption of information acquired prior to the injury, i.e. retrograde amnesia, as well as information to be learned after the injury, i.e. anterograde memory. Finally, it is equally important to specify whether a dissociation is observed in the patient's performance in terms of the verbal versus non-verbal modality of the stimulus presentation. Data on sensory modality selective impairments can be pivotal in the conception of rehabilitation programmes.

Anterograde Memory

The clinician may seek to assess the patient's *verbal* memory performance according to the *encoding* condition, i.e. presenting a control-encoding task such as Grober and Buschke's (1987) Test. This test consists of 16 words belonging to 16 different categories and presented on cards containing four words at a time. The patient is asked to read aloud and to point to each item (e.g. harp) following the examiner's indication of a category (musical instrument). When the four items are thus learned, the card is removed and the patient is given the four categories as a cued immediate recall. If the patient is unable to respond, the item is shown again and the same steps as above are carried out until every item is encoded. The learning phase is achieved when all or nearly all the items have been encoded (otherwise the test should be discontinued). Three recall trials follow the encoding of the 16 items and each of them consist of free recall immediately followed by cued recall of the words the patient was unable to retrieve spontaneously. The three recall trials show the patient's learning capacity. Results on the Grober and Buschke Test are often compared with learning tests with no control-encoding conditions such as the Auditory Verbal Learning Test (AVLT; Rey, 1964). This very frequently used task consists of five presentations of a list of 15 unrelated words and a second list that is presented once. Whenever the learning curve is reliably better on the Grober and Buschke Test than in the AVLT, the remaining of the memory examination is carried out at a slow pace to aid acquisition of new material. This should help to characterize accurately the patient's memory function. If the encoding process appears to be impaired independently of the test, the clinician might seek to address the encoding deficit itself: is it due to the patient's difficulty in engaging in deeper levels of information processing? This difficulty was reported in diencephalic lesions as, for instance, Korsakoff amnesia by Butters and Cermak (1980), who demonstrated that patients failed to encode new information because they could analyse only the features representing the 'shallow' levels of verbal information.

Deficits in the *storage* stage of the newly acquired information have also been reported in cases of faster than normal rates of forgetting. Such deficits are interpreted within the consolidation of information theory (see Squire & Alvarez, 1995). Storage or maintenance deficit is not developed in the present entry since consolidation theory is both better viewed taking into account some single case studies of temporally graded retrograde amnesia (e.g. Manning, 2002) and more readily developed in relation to neuropsychological research topics than in connection to neuropsychological assessment.

Differences in *retrieving* information in anterograde memory is documented by recall versus recognition tests. However, no ready comparisons can be drawn between them since recall and recognition elicit different brain areas and memory mechanisms. Some verbal learning tests include a recognition section (e.g. the Grober and Buschke Test or the California Verbal Learning Test, CVLT; Delis et al., 1987), providing the possibility to illustrate the two retrieval conditions within the same test. However, it may be useful to obtain data on the patient's recognition memory with no previous learning of verbal information. Warrington (1984) developed the Recognition Memory Tests for Words and for Faces, with the aim to detect minor deficits of memory. The test consists of 50 words that are shown to the patient, one at a time during three seconds. The patient's attention is controlled (see Table 1) during the encoding phase of the task. Immediately after the presentation of the items, the patient performs a forced-choice recognition task with distractors. This test is more resistant to the effects of anxiety and depression (Coughlan & Hollows, 1985); however, the main interest of the test is to allow the clinician to detect selective verbal or non-verbal memory disorders.

Within the *non-verbal* modality, visual reproduction and visual recognition tests are routinely

used in neuropsychological assessment of memory. The most widely known line drawing, abstract design, visual memory reproduction test is probably the Rey Complex Figure (Osterreith, 1944; Rey, 1964). Scoring procedures for this (Lezak, 1995) and some other reproduction tasks (e.g. the Visual Retention Test by Benton, 1962) have norms for different groups of brain-damaged patients and normal individuals. Apart from the recognition memory test for faces, Warrington (1996) also developed the Topographical Memory Test, which allows identification of dissociations between the ability to recognize places as compared with routes.

Retrograde Memory

Besides the difficulty of learning new material, patients presenting memory loss may also show a defective performance when asked to retrieve events, both autobiographical and public, which occurred prior to the brain pathology. When retrograde amnesia is present, the clinician needs to know how far back it extends. Therefore, retrograde memory tests should include the possibility to show the patient's performance on material drawn from different periods.

There are several methodological problems related to retrograde memory tests. Thus, for instance, retrograde memory tests for public events have items related to events that range from recent to remote periods. This implies that the tests must be constantly updated, which being impracticable, restrains considerably the possibility of obtaining a standardization based on wide range population samples (see Lezak, 1995).

Past memories of *personal events* are often tested by means of the Autobiographical Memory Interview (AMI; Kopelman et al., 1990). The test is divided into two sections in order to cover factual knowledge about personal semantic information and recollection of autobiographical incidents. It is designed to elicit data across the whole life span: childhood, early adult life and recent life.

A further complementary task is the Galton–Crovitz Test (see Graham & Hodges, 1997). The patient is asked to produce a recollection based on each word from a pool of 20 items (e.g. party, friend, book, prize, film, etc.). Each word is given the number of times necessary to cover different periods of life (e.g. 0–18 years; 19–33 years; 34–49 years). The patient is encouraged to say as much as possible and to give as many details as possible. It is suggested to score responses using a 0–5-point scale (from 'don't know' to detailed, specific single events).

Past memories of *public events* are tested using the Famous Faces Test. A number of celebrities from the past are presented to the patient, who is asked to name the person or to provide as much information as possible concerning his/her occupation, political party, etc. The test includes personalities who were famous throughout different decades.

Kapur et al. (1989) developed the Dead/Alive Test, which consists of 30 personalities who have died and 10 living celebrities. This task assesses memory for people who were famous over the past 30 years. The patient is requested to indicate if the celebrity shown to him/her is dead or alive, whether he/she has been killed or has died of natural causes. Finally, the patient is asked to date the personality's death in five-year bands.

FUTURE PERSPECTIVES AND CONCLUSIONS

Over the past two decades, the detailed analysis of patients presenting memory loss has revealed important theoretical and clinical implications, which show both the necessity to separate assessment of memory from other cognitive functions and to conceptualize memory as a predominantly heterogeneous system. The aims of the neuropsychological assessment of memory have consequently moved from achieving a global result to that of obtaining a set of scores. The latter approach would show the patient's deficits and preservations in a wide range of specific aspects of memory as, for instance, in relation to the onset of the illness or in terms of long-term memory contents or input modalities. Finally, the memory process, encoding, storage and retrieval should be viewed as contributing to the formation of memory traces, each in a specific, different and complex way. Future perspectives are related to the integration of knowledge and applied techniques from different scientific domains. The contribution of functional brain imagery seems crucial in the attempts of improving our understanding on memory processes and the consequent development of sophisticated and sensitive memory tests.

MENTAL RETARDATION

INTRODUCTION

Intellectual disability comprises a heterogeneous group of people, who in their school years are singled out as having general difficulty in learning, and in adult life as having limitations in their independent community functioning. The present entry describes how to assess

intelligence and cognitive processes, adaptive skills and social functioning and behavioural problems in persons with intellectual disability. We use intellectual disability in addition to mental retardation because it is currently the broadly accepted scientific definition for identifying the population group diagnosed with adaptive and intellectual limitations. The term 'mental deficiency' was widely used during the 1970s and beginning of the 1980s, but by the second half of the 1980s it had been replaced by 'mental retardation'. Nowadays, the preferred term for professionals and scholars worldwide is 'intellectual disability'.

Intellectual disability cannot be understood as a characteristic of the individual, despite the fact that it has traditionally been classified as a medical or psychiatric disorder. Since 1992, with the significant paradigm shift in the concept of mental retardation proposed by the American Association on Mental Retardation (AAMR) (Luckasson et al., 1992), it has been considered that mental retardation refers to substantial limitations in present functioning. This means that we are now emphasizing individuals' functioning instead of their characteristics. Individuals' functioning is understood as the result of the adjustment between personal abilities and characteristics, and environmental expectations. Consequently assessment should not focus as much on the individual as on the environment around him.

PRESENT CONCEPT OF INTELLECTUAL DISABILITIES

The present conceptual approach to the definition of intellectual disability is not a medical model, although the medical model can describe the aetiology, nor is it a psychometric or psychopathological model, although the former is fundamental for determining competence in intelligence and the latter can describe the thoughts or behaviours experienced by a person with mental retardation. The AAMR proposes a functional model based on the integration of multidisciplinary and multidimensional perspectives addressed at specifying the needs of the individual in order to determine the type and intensity of the supports needed. Mental retardation is not considered an absolute feature of the individual but the expression of the interaction between the person with limited intellectual functioning and the environment. To talk about mental retardation does not mean to talk about people with certain characteristics, but about the restricted functioning of people with specific personal limitations.

We should not suppose that mental retardation is pervasive throughout the lifespan of the individual. In fact, the prevalence of mental retardation in adult life decreases because the requirements of social and cultural environments are not as high as the demands of school regarding educational performance and disciplined group behaviour. The existence of mental retardation is defined by the evaluation of the need to provide supports for the normal functioning of the individual.

Although a multidisciplinary approach is proposed, psychology is the discipline which tends to focus more on the individual and their interaction with the environment, and therefore psychologists should organize and define key decisions in the assessment process (Jacobson & Mulick, 1996). Mental retardation assessment consists of a formal diagnosis and the functional description of strengths and weaknesses of the individual, together with his needs. A competent person will carry out the diagnosis through psychological tests, but in order to have an appropriately developed functional description of the individual it will need to be devised by a multidisciplinary team. The team should be made up of people who spend greater time with the person, both within a family context and through supporting services and programmes.

DIAGNOSTIC CRITERIA FOR INTELLECTUAL DISABILITIES

Despite some significant discrepancies, the American Association of Psychology (APA) and the American Association of Mental Retardation (AAMR) coincide in the essential features that the evaluator has to bear in mind in order to identify and diagnose a person with intellectual disability. The three criteria are (Editorial Board, 1996; Luckasson et al., 1992) as follows.

Significant Limitation in General Intellectual Functioning

The significance criterion refers to an IQ that is two or more standard deviations below the mean. The assessment of IQ has to be carried out by a qualified psychologist applying one or more individual tests with the appropriate psychometric guarantees. Moreover, it is advisable to confirm the assessment with data from the application of other tests in the assessment process.

Significant Limitations in Adaptive Functioning which Exist Concurrently with Intellectual Limitations

For this criterion, the APA proposes to use an individual, comprehensive measure of adaptive behaviour. In this case, the significance criterion would be similar to those above: a global score of two or more standard deviations below the mean of the population in that measure. However, the AAMR substantially changes this criterion and defines it as limitations in two or more of the following adaptive skill areas: communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work. Such areas lead to a categorization of the individual's general behaviour in order to facilitate the identification of needs and favour the specification of support strategies, bearing in mind the comparative age of the person under assessment. Hence, we obtain more operative criteria than those of the APA in order to promote the interface between assessment and intervention.

Intellectual Disability Should Manifest Itself before Age 18

This criterion results from the fact that in Western cultures an individual assumes the function of an adult at 18, since it is considered to represent the completion of a person's development. In other cultures, due to different features regarding the individual's developmental process, different age criteria may be appropriate. The APA has proposed the extension of such a limit up to 22 years, since the present situation allows for general longer educational stages and family dependence.

PROCESS OF EVALUATION OF MENTAL RETARDATION

Basic Assumptions in the Process of Evaluation

In order to avoid serious mistakes in the diagnosis of intellectual disabilities, we should begin with a series of assumptions based on the experience of previous decades in the evaluation of people with intellectual disability. According to the system proposed by the AAMR in 1992, we might differentiate four different assumptions, which are inseparable from the definition. The evaluation has to take into account these assumptions in order to take the appropriate decisions about the evaluation process.

First, an evaluation is considered to be valid when it takes into account cultural and linguistic diversity of the individual, together with possible differences in communicative and behavioural facets. Applicable tests and procedures must be based on this assumption. If not, we would be discriminating against all those who form part of cultural minorities or have special communication characteristics.

Secondly, the determination of limitations in adaptive skills must be made in relation to a typical community environment of similar age peers. The evaluation of adaptive skills becomes significant and useful when it is carried out within the natural context where the person studies, works or spends their leisure time. And, of course, we are always talking about similar environments to those of people of a certain age.

Analyses and assessments should not be exclusively focused on the individual deficiencies. On the contrary, they should recognize that together with adaptive limitations there are strengths in other areas, and we have to take them into account when treatment is established. Supports to any person must be based not only on the analysis of limitations but also on an improved knowledge of their own possibilities in different aspects of behaviour.

Finally, it is accepted that the functioning of persons with intellectual disability will improve if they are provided with appropriate supports for a continued period of time. Consequently, every person can improve no matter the extent and severity of the deficiencies. Such a statement is broadly the result of innovative input from the

behavioural approach to education and treatment of people with intellectual disabilities. Towards the end of the 1970s, behaviour modification analysis and techniques proved to be efficient and allowed us to undertake professional work with children and adults that were traditionally segregated from educational and therapeutic programmes on the grounds that they were ineducable. Success in the treatment of disruptive behaviours (self-lesion, stereotyped behaviours, aggressions, etc.) and the development of support programmes for populations with greater deficiencies showed that every person can have, and has, the right to improve and enhance his quality of life.

Evaluation of Intelligence Limitation

The criterion to determine the existence of a significant intellectual limitation is a score in conceptual intelligence performance of about two or more standard deviations below the mean. This implies a standard score of approximately 75–70 or below, based on scales with a mean of 100 and a standard deviation of 15. Such a score range recognizes the importance of a possible measurement error in assessment instruments. If standardized measures are not appropriate for the actual case (because of cultural diversity, for example), clinical opinion should be used. In such a case, a significant limitation means a performance below that of approximately 97% of the people in the reference group (in terms of age and cultural environment).

The most used instruments to assess intellectual functioning are: Stanford–Binet Intelligence Scale (Thorndike, Hagen & Sattler, 1985), Wechsler scales (Wechsler Intelligence Scale for Children – III [Wechsler, 1991]; Wechsler Adult Intelligence Scale – Revised [Wechsler, 1981]; Wechsler Preschool and Primary Scale of Intelligence [Wechsler, 1967]), and the Kaufman Assessment Battery for Children (K-ABC, Kaufman & Kaufman, 1983).

The results of the intelligence test are only one part of the whole process of intelligence assessment. Since as individual's functioning in situations of daily life must be consistent with scores in standardized measurements, if there is no such consistency we should put into doubt the validity of the measurements obtained in those tests. Thus, it is also indispensable to use other assessment measures with more flexibility and ecological validity (direct observation of behaviour, clinical interviews and analysis of the individual's history or data) and clinical judgement to determine whether the IQ score is valid or not for a specific person.

Evaluation of Limitation in Adaptive Functioning

The evaluation of adaptive skills is essential for assessing actual limitations of the individual and to know how to help or provide an efficient support. Traditionally, procedures have been designed to find a general measure of adaptive behaviour, but there has been a great deal of confusion over what aspects should be included in the measure, since the concept has not been clearly formulated. The 1992 proposal by the AAMR meant an important advancement and provided new orientation in the diagnosis and assessment of adaptive functioning.

Instead of looking for a general measure of adaptive behaviour, we refer to ten adaptive skill areas (cited in the second diagnostic criterion), with specific and differentiated content which allows for habilitation and rehabilitation programme planning. The purpose is not, therefore, limited to diagnosis, but assessment is directly linked to intervention. And the higher or lower importance of those areas is related to the relative age of the person and developmental level. On the other hand, pathological, disruptive, or maladjusted behaviours are included in another area, referred to as psycho-emotional, and they are not included in the adaptation area.

Existing tests to measure general adaptive behaviour are different in nature and some help is required in the general diagnosis of mental retardation and others for the in-depth analysis of an individual's competencies, with the final aim of intervention. The most used instruments are: Adaptive Behaviour Scales (ABS) (Nihira, Foster, Shellhaas & Leland, 1974), School Edition of the ABS (Lambert & Windmiller, 1981), Vineland Adaptive Behaviour Scales (Sparrow, Balla & Cicchetti, 1984), Scales of Independent Behaviour (Bruininks, Woodcock, Weatherman & Hill, 1984) and the Comprehensive Test of Adaptive Behaviour (Adaptive Behaviour Global Test) (Adams, 1984).

Adaptive skill evaluation should be undertaken from a clinical standpoint, more than a psychometric one. Together with the information from the above-mentioned scales, it is advisable to gather information about the individual's closer environment (the more the better, and always on the most reliable information). Sometimes, direct behaviour observation is required. In this way, we may obtain a clinical judgement based on the convergent validity of consistency of the data obtained through different sources and situations. With such changes, we are aiming at developing more efficient and accurate decisions for diagnosis and programme planning.

Evaluation of Psycho-Emotional Problems

People with mental retardation do not always exhibit altered behaviours in the psycho-emotional domain. On the contrary, most of them present similar characteristics to the non-disabled population. However, the prevalence of psychological disorders or psycho-emotional alterations is quite a lot higher than it is in populations without mental retardation. Consequently, we need a specific approach to the evaluation of this area in all persons with intellectual disability, even though we often find people who exhibit good psychological well-being and, therefore, do not require intervention.

Problems in the psycho-emotional domain can be maladaptive or challenging behaviour, or psychopathological disorders related to formal psychiatric designations (Olley, 1999; Olley & Baroff, 1999; Verdugo & Gutiérrez, 1998). Among maladaptive behaviours we find stereotypical behaviour, self-injury and problematic sexual behaviour. Among psychopathological disorders: anxiety, mood, depression and schizophrenia.

If we refer to behavioural problems in populations with intellectual disability, very often it is the contexts they are in that fails to promote the development of appropriate behaviours. The existing environments involuntarily promote and foster maladaptive repertoires, which require professional intervention in order to be minimized or eliminated. Consequently, evaluation should undertake an accurate analysis of the environment surrounding the individual. The evaluation of behavioural problems should be based on a functional analysis. Functional analysis aims at discovering the role behaviour is playing. We analyse the possible functional relationship between a feature of the environment and the behaviour exhibited by the person. The essential presupposition to bear in mind is that every problem exhibited by the individual serves a specific purpose, they are strategies to achieve something. And changing the behaviour will require the identification of that purpose behind the individual's behaviour.

FUTURE PERSPECTIVES AND CONCLUSIONS

Nowadays we are still witnessing significant changes in our understanding of people with intellectual disabilities and, in light of this, in how to evaluate them. A long time ago we shifted from biological approaches to psychometric and psychopathological models, and currently there is a consensus being formed about a functional model addressed at efficiently designing the best possible supports for the individual. Such a model, multidimensional and interdisciplinary in nature, does not consider people with problems from a psychopathological perspective, but as persons who are different in their manifestations and behaviours. People with intellectual disabilities require both evaluation and intervention based on present scientific principles, but should not always be identified as individuals with psychological disorders. It is true that they experience these disorders more often than other people and, consequently, they have to be evaluated in this domain or via these dimensions, but most of them will not require help in this field.

The changes in the near future will take place in the field of support definition, intelligence evaluation, adaptive behaviour assessment and the very understanding of psychological disorders in the population. The criterion of significant limitation of intelligence has always been associated with the definition of mental retardation or intellectual disability. And its measurement, although approached from comprehensive perspectives and using different procedures, is essentially psychometric, based on individual tests. The next few years will witness an in-depth analysis of these approaches, but not a significant shift in the long-standing criteria.

The criterion of limitations in adaptive skills is more prone to immediate change. In fact, among professionals, it has always been the most discussed and polemical criterion (Langone, 1996). In the 21st century, due to limitations as a general measure of adaptive behaviour and as suggested by the APA (Editorial Board, 1996), we may not refer any more to the list of the ten adaptive areas previously proposed by the AAMR (Luckasson et al., 1992). Instead, we are witnessing the emergence of an understanding based on a theoretical framework or tripartite intelligence, which emphasizes the analysis of limitations in practical, conceptual, and/or social adaptive skills (Luckasson, 2000). The implications of such an approach will guide the organization of the analysis of individuals' competencies and support needs. And this should bring about substantial changes to the ten adaptive areas proposed by the AAMR in 1992.

Finally, the psycho-emotional area will produce the most innovative research and improved evaluation. On the one hand, the criteria will be broadened to analyse this area from a psychological well-being related perspective (Verdugo, in press), and the aim of evaluation will be to obtain useful information for the enhancement of the personal satisfaction of the individuals. On the other hand, research will suggest new keys to improve our understanding of individuals' psychopathology and special characteristics of this population. So far we have only taken a few modest steps towards our final goal.

MOOD DISORDERS

INTRODUCTION

Mood disorders are generally defined according to criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV; APA, 1994). While the DSM-IV lists 10 mood disorders, only major depressive disorder (MDD) and bipolar disorder (BD) will be addressed in this entry. MDD is defined as exhibiting either depressed mood or loss of interests or pleasure most of the day nearly every day for at least 2 weeks and accompanied by at least five of the following symptoms: (1) change in weight or appetite; (2) insomnia or hypersomnia; (3) psychomotor agitation or retardation; (4) fatigue or loss of energy; (5) feelings of worthlessness or excessive guilt; (6) poor concentration or indecisiveness; and (7) suicidal ideation or attempt. BD involves a manic episode for at least 1 week and may or may not involve the symptoms of MDD. Symptoms of a manic episode include either euphoria or irritability and at least three of the following symptoms: (1) inflated self-esteem or grandiosity; (2) decreased need for sleep; (3) talkativeness or pressured speech; (4) flight of ideas; (5) distractibility; (6) increase in activity level; and (7) excessive involvement in pleasurable yet risky activities.

This entry will first address difficulties in assessing MDD and BD. Second, several assessment devices will be described. Third, the need for additional devices will be noted. Finally, it will be concluded that assessment devices for MDD and BD should be multivariate and include not only symptoms of disordered mood but also causal and maintenance factors that can guide prevention and treatment strategies.

DEFINITIONAL CHALLENGES TO ASSESSMENT OF MOOD DISORDERS

DSM-IV criteria for MDD and BD are quite heterogeneous and some are ill-defined. For MDD, either depressed mood or anhedonia must be present most of the time, but what constitutes 'most' is not specified. Furthermore, it is unclear how these two criteria are measured separately. Is it possible to exhibit dysphoria but still exhibit pleasure? Another measurement challenge is that the DSM-IV weighs all seven symptoms of MDD equally. If a person is very sad and suicidal but has normal appetite, sleep pattern, and energy level, is this person not disordered? In clinical settings, suicidal people are given emergency treatment but, as discussed below, assessment devices for MDD would not alert the clinician of a serious problem. Therefore, another measurement challenge is how to weigh the significance of each of the seven symptoms that accompany dysphoria or anhedonia.

For BD, the defining symptom to assess is either euphoria or irritability. Excessive happiness and excessive anger are different emotional states that involve different cognitions and behaviours. It is unclear why they are not recognized as separate mood disorders. There are few assessment devices for BD and this definitional confusion may be one reason this disorder has been difficult to measure.

Another challenge to the measurement of MDD and BD is the temporal criteria for diagnosis. Identification of symptoms lasting 2 weeks for MDD and 1 week for BD requires accurate retrospective reporting which is subject to not only memory bias but also the very symptoms of the disorders (e.g. difficulty concentrating and distractibility). While continuous observation or self-monitoring may obviate this issue, most techniques for assessment of mood disorders are based on a single administration of the device.

ASSESSMENT DEVICES

There are at least 50 instruments designed to assess mood disorders (Nezu, Ronan, Meadows & McClure, 2000). Most of the instruments assess MDD symptoms and very few measure manic symptoms relevant to BD. The instruments include structured interviews, observational and

clinician-rated protocols, and self-report inventories. A sampling of instruments with strong psychometric support and cost-effectiveness for both screening and diagnosis will be summarized. Instruments designed for special populations (e.g. mentally retarded, schizophrenics, older persons, etc.) will also be described.

Structured Interviews

The Diagnostic Interview Schedule (DIS; Robins, Helzer, Croughan & Ratcliff, 1981) is available in several languages and in adult and child versions. It is highly structured, takes 90 to 120 minutes to administer, and yields diagnoses for MDD, BD, and other DSM-IV disorders. Its advantages include being conducive to administration by a layperson while disadvantages include lack of norms. The Structured Clinical Interview for DSM-IV Axis I Disorders (SCID; First, Spitzer, Gibbon & Williams, 1997) is designed for adults and adolescents. It is semi-structured, takes 45–90 minutes to administer, and measures both MDD and BD. Advantages include being briefer than the DIS-IV while disadvantages include lack of norms. The Kiddie-Schedule for Affective Disorders and Schizophrenia for School-Age Children – Present and Lifetime version (K-SADS-PL; Kaufman et al., 1997) is semi-structured, takes 35–75 minutes to administer, and yields diagnoses for MDD, BD, and other DSM-IV disorders. Advantages include obtaining data from both the child and a caregiver while disadvantages include lack of norms.

The Clinician-Administered Rating Scale for Mania (CARS-M; Altman, Hedeker, Janicak, Peterson & Davis, 1994) was developed to improve existing mania rating scales, using 15 items that correspond to DSM-IV criteria for manic and psychotic symptoms. The CARS-M is semi-structured, takes 15–30 minutes to administer, and yields a total score and two subscale scores. Advantages include standardization of administration, delineation of mania from psychotic symptoms, and evidence demonstrating the measure's specificity to mania. Also, an initial study on its Spanish version reported acceptable psychometric properties (Livianos et al., 2000). Disadvantages include its inappropriateness for assessing depression in mixed and schizoaffective states, and for use among adolescents and the elderly.

Clinician-Rated Protocols

Few observational devices have been designed to assess either MDD or BD, and most devices are designed for special populations. The Calgary Depression Scale for Schizophrenia (CDSS; Addington, Addington & Maticka-Tyndale, 1993) is designed to discriminate mood disorder and schizophrenia symptoms among all ages. The CDSS includes both semi-structured interview questions and observer Likert-type ratings of MDD symptoms, takes at least 30 minutes to administer, and yields a total score. Advantages include rapid administration and availability of norms to guide score interpretation. Disadvantages include restriction to clinical settings with raters familiar with both mood disorders and the range of schizophrenic symptoms that overlap and affect both self-report and observational ratings. The Psychopathology Inventory for Mentally Retarded Adults (PIMRA; Matson, 1988) consists of clinician and observer (e.g. caregiver, work supervisor) ratings of symptoms of eight disorders and an affective disorder scale representing mostly MDD behaviours. The PIMRA takes 30–45 minutes to administer (10 minutes for the affective scale) and yields a total score and eight subscale scores. Advantages include multi-method assessment while disadvantages include lack of norms. The Cornell Scale for Depression in Dementia (Alexopoulos, Abrams, Young & Shamoian, 1988) is also multi-modal, involving Likert-type clinician ratings of MDD symptoms based on both client and caregiver responses to 19 items. It is designed for individuals of all ages exhibiting symptoms of dementia while maintaining the ability to communicate, takes about 30 minutes to administer, and yields a total score interpreted against the mean of a small normative sample. Advantages include standardized procedures for reconciling the score when there are differences between clinician ratings of client and caregiver responses. Disadvantages include the need for raters to be highly trained in both mood disorders and organic brain disorders.

The Brief Psychiatric Rating Scale (BPRC; Overall & Gorham, 1962) and its expanded version, BPRS-E (Van der Does, Linszen, Dingemans, Nutger & Scholte, 1993), assess general psychopathology including mood disorders. The standard version has 18 items, takes up to 45 minutes to administer, and yields a total score and five subscale scores. Advantages include

its comprehensiveness, while disadvantages include lack of specificity for any disorder, extensive training required to ensure reliability and validity of ratings, and reported higher interrater reliabilities for diagnoses within the psychotic than non-psychotic range (Hafkenscheid, 1993). Of the few existing mania scales, the commonly used Mania Rating Scale (Young, Biggs, Ziegler & Meyer, 1978) has 11 items, takes 15–30 minutes to administer, and yields a total score. Advantages include its comprehensiveness and acceptable interrater reliabilities. Disadvantages include lack of standardized administration, unequal weight assigned across item scores, and lack of evidence for its specificity for BD.

Unlike symptoms rating scales, the recently developed National Institute of Mental Health prospective Life Chart Methodology (NIMH-LCM-p or LCM; Denicoff et al., 1997) and its patient-rated version (Leverich & Post, 1998) assess degree of functional impairment due to the course of BD. The LCM has five daily monitoring items, including a significant events rating and an overall rating of functional impairment due to mania or depression. Advantages include standardized administration, facilitation of individualized short- and long-term course and treatment monitoring, delineation of impairments due to mania and depression, and ease of analyses when using the computerized version. Disadvantages include partial reliance on the patient's recall of information and lack of symptom monitoring relevant to illness and DSM-IV criteria.

Self-Report Inventories

The most common type of assessment device for mood disorders is the self-report questionnaire, and most of these are designed to assess MDD. The most widely used measure for adults is the Beck Depression Inventory (BDI-II; Beck, Steer & Brown, 1996). The BDI is designed for adolescents and adults, contains 21 items, takes 5–10 minutes to complete, and yields a total score. Advantages include extensive psychometric support, provision of cutoff scores, and a version in Spanish. Disadvantages include failure to associate cutoff scores with MDD diagnosis and equal weighting of items. The Zung Self-Rating Depression Scale (Zung, 1965), designed for adults, is another 'gold standard' of self-report measures with strong psychometric support. It contains 20 items, takes about 5 minutes to complete, and yields a total score. Advantages include rapid administration and free availability on the Web (www.welbutrin-sr.com/eval/zung.htm). Disadvantages are similar to those of the BDI. The Children's Depression Inventory (CDI; Kovacs, 1992) is designed for ages 7–17 years, contains 27 items, and takes 10–15 minutes to administer. Advantages include standardized scores, a 10-item short form, and translated versions in 10 European languages. Disadvantages include poor discrimination from other childhood disorders. The Geriatric Depression Scale (GDS; Yesavage et al., 1983) is designed for adults aged 65 and older. It contains 30 items, can be administered orally or in written form, and takes about 30 minutes to complete. Advantages include flexibility in administration to accommodate physical or cognitive impairment, free availability on the Web at www.stnford.edu/~yesavage/GDS.html, and translated versions in various Asian and European languages. Disadvantages include lack of norms and cutoff scores.

One of the few instruments designed to measure both MDD and BD symptoms is the Multiple Affect Adjective Checklist – Revised (MAACL-R; Zuckerman & Lubin, 1985). The MAACL-R assesses anxiety, depression, hostility, positive affect, and sensation seeking among adolescents and adults. It contains 132 items, has two forms for state and trait affect, and takes 5–10 minutes to complete each form. Advantages include standardized scores and assessment of a range of moods. Disadvantages include omission of related symptoms of mood disorders. The most useful instrument for assessing BD is the General Behaviour Inventory (GBI; Depue et al., 1981) designed for adolescents and adults. It contains 73 items and provides cutoff scores for subtypes of BD, such as cyclothymia. Advantages include the strongest psychometric support for any self-report measure of BD, making it more cost-effective than clinical interviews. Disadvantages include failure to detect BD when symptoms are infrequent or rapid cycling (Klein, Dickstein, Taylor & Harding, 1989).

The patient self-report version of the previously mentioned LCM (Leverich & Post, 1998) contains four items that assess daily functional impairment severity due to mania or depression. Along with the above reported advantages, one disadvantage is the possible non-compliance by

BD patients in completing daily assessments, particularly in non-inpatient settings.

FUTURE PERSPECTIVES

While there has been good progress in developing assessment devices for MDD, there is a need for instruments designed to assess BD and other mood disorders. Because most instruments are available in English only, translated versions are needed. Also, few instruments are available for people who cannot verbally communicate symptoms of mood disorders, indicating a need for multi-modal instrumentation so that assessment can be conducted with information from observation in natural and analogue settings, self-report, observer's report, and psychophysiological indices.

There is also a need for instruments that assess not only the symptoms of mood disorders, but also the theoretical causal and maintenance factors that would guide prevention and treatment planning. One such instrument is the Elder Life Adjustment Interview Schedule (ELAIS; Dubanoski, Heiby, Kameoka & Wong, 1996). The ELAIS is a structured interview and contains scales that assess depression along with situational conditions, health status, and behavioural competencies related to mood regulation. The ELAIS also contains scales that assess cognitive functioning and response sets to check for reliability of responses to interview questions. The ELAIS takes about an hour to administer and is available in English and Japanese languages. A self-report version for adolescents and adults is under development by the present authors.

CONCLUSIONS

The advancement of instruments to assess MDD has corresponded with the development of integrated theories (e.g. Eifert & Evans, 1990). The slow development of instruments to assess BD reflects the lack of clarity of the disordered moods involved (i.e. both euphoria and irritability) and little theoretical understanding of causal and maintenance factors. Most theories of BD focus on organic determinants for which there are no medical diagnostic procedures. A recent psychological theory of BD (Reidel, Heiby, & Kopetskie, 2001) suggests that assessment of this condition include measures of situational conditions (e.g. pleasant events and obstructions to goals), health factors (e.g. sleep deprivation), and behavioural competencies (e.g. skills to engage in risky activities and deficit predictions of long-term negative consequences). This theory could guide the development of a multi-scale assessment device for BD.

MOTIVATION

INTRODUCTION

Why do some people spend their time thinking about accomplishing tasks whereas others tend to reflect on their relationships? What personal characteristics determine whether people will flourish versus flounder in particular domains? Why are some people successful at reaching their personal goals whereas others fail when faced with distractions and obstacles? Why do some individuals display enhanced well-being after reaching their goals whereas others do not? These are the types of questions that motivational researchers have sought to answer over the past 50 years. The classic approach to these questions involved the assessment of individual differences in the strength of psychological needs for achievement, affiliation, and power. Such needs were conceptualized as relatively stable dispositions that are learned early in life and that predispose individuals to strive for certain classes of goals. Whether such needs are best measured through content-analysis of verbal material or via self-report of goal preferences has been the topic of lively debate. More recently, an alternative conception of needs as necessary psychological

nutriments rather than collections of desires has been proposed. Three essential needs have been identified – for autonomy, competence, and relatedness – and the focus has shifted to examining the extent to which goal selection and subsequent self-regulatory efforts support versus hinder the satisfaction of these needs.

ASSESSING MOTIVES IN IMAGINATIVE STORY CONTENT

Fifty years have passed since McClelland, Atkinson, and their colleagues (1953) began a research tradition founded on the assumption that there is a pattern and organization to the flow of human behaviour which can partly be understood in terms of underlying psychological motive dispositions such as the need for achievement or the need for affiliation. These psychological motives were conceptualized as enduring features of personality that energized, directed, and selected wide varieties of behaviour and experience. Individual differences in the strength of various motives were thought to be most directly assessed by examining the content of people's imaginative thoughts. This belief was based on the assumption that expressive behaviours, such as fantasies, reflected internal motive dispositions more uniquely than did perception, action, or judgement which are strongly influenced by determinants in external reality (McClelland, 1988).

The most widely used motive scoring system was developed to assess the need for achievement. Respondents are asked to write brief stories in response to four to six ambiguous picture cues (e.g. a picture of an architect at his desk with a photo of his family in front of him). The written stories are coded according to a detailed and explicit scoring system. Scoring is based on the presence and level of elaboration of achievement themes. The scoring system was developed by comparing the thematic content of stories told by individuals whose achievement motive had been experimentally aroused versus participants in a neutral condition. The nAch scoring system is objective, quantitative, and yields high levels of agreement among trained coders. It has been validated with participants from cultures as diverse as Germany, Japan, and Brazil. Similar scoring systems were developed to assess the needs for power and affiliation. The most recent versions of the content-coding systems for social motives are available in the *Handbook of Thematic Content Analysis* (Smith, 1992). (Table 1 provides references for all instruments discussed in the present entry.)

Academic Motivation Scales	1997	Vallerand et al.
Goal Motivation Scales	2001	Sheldon
Self-Efficacy	1997	Bandura
Achievement Attributions	1970	Weiner & Kukla

Achievement motivation is defined as a concern with doing things better or with surpassing standards of excellence (McClelland & Koestner, 1992). Early studies indicated that achievement motivation predisposed individuals toward moderate risk-taking in performance situations (Atkinson, 1957). Later studies showed that achievement motivation is related to superior performance when activities are moderately challenging, provide performance feedback, and encourage personal responsibility for outcomes (McClelland, 1988). Among adult men, achievement motivation promotes a positive orientation toward work, in general, and is particularly predictive of success at entrepreneurial activities. Among adult women, the relation of nAch to work outcomes is strongly affected by whether their values are family-centred or career-oriented. The relation of achievement motivation to school performance has been shown to depend on the presence of challenge and feedback. The dynamics of achievement-related actions were extensively discussed by Atkinson and Birch (1970).

Power motivation is defined as a concern with having an impact on others (Winter, 1992a,b). Men with strong power motivation exhibit the

following characteristics: (a) they strive to gain recognition by joining organizations and pursuing leadership positions; (b) they pursue occupations which offer opportunities for exerting influence; (c) they are drawn to competitive activities and perform well at them; (d) they experience difficulties in their intimate relationships with women; (e) they are likely to suffer from health problems such as high blood pressure, poor immune functioning, and drinking problems. Women who are high in power motivation have also been shown to strive to gain recognition and to pursue careers that offer the opportunity for exerting influence; however, among women, power motivation is not related to negative outcomes such as relationship difficulties and health problems. Self-control and experience with responsibility can moderate many of the negative outcomes associated with strong power motivation in men. The unique combination of high power motivation and high self-control has been shown to be strongly associated with managerial success.

Affiliative motivation is defined as a concern over establishing, maintaining, or restoring positive relations with others (Koestner & McClelland, 1992). Affiliative motivation has been related to the amount of time spent interacting with others and possessing a sympathetic and accommodating interpersonal style. However, because affiliative motivation has been associated with social anxiety and lack of popularity among peers, it was suggested that nAff is best conceived as a measure of affiliative anxiety or fear of rejection. Intimacy motivation captures the positive aspect of affiliative motivation and has been related to relationship quality and psychosocial adjustment (McAdams, 1992a,b).

Despite early criticism, fantasy-based measures of motives have been shown to display adequate test–retest reliability when they are assessed under relaxed conditions and with appropriate instructions (McClelland, 1988). Furthermore, fantasy motives have been shown to possess considerable predictive validity in areas such as task performance, occupational success, relationship patterns, and health outcomes. The relation of social motives to various criteria can be most clearly established when environmental factors (e.g. incentives and opportunities) and non-motivational person variables such as skills, self-schemata, and sex-roles are considered. For example, Winter et al. (1998) recently showed that impact of the need for power and affiliation on career choice and relationship outcomes depends importantly on whether or not individuals are introverted or extroverted. Many of the positive correlates of these motives were only evident for those who were relatively extroverted.

DISTINGUISHING MOTIVES ASSESSED IN FANTASY AND SELF-REPORT

Self-report scales were developed to replace the fantasy-based motive measures because they were thought to be more reliable, as well as more efficient to administer and score. Edwards designed a self-report inventory for motives in 1954, but a large number of other such inventories have since been introduced (e.g. Jackson, 1974). These inventories typically offer excellent psychometric credentials with scale internal consistencies and test–retest reliabilities ranging between 0.60 to 0.80. However, two problems with using self-report motive inventories are that respondents may (1) be unaware or unable to report on their motivational state; and (2) shade their responses in a socially desirable direction.

More importantly, self-report measures of motives rarely correlated significantly with similar measures derived from coding associative thought (Spangler, 1992). This fact was reported first in 1953 by McClelland et al., and has been confirmed many times since then. McClelland, Koestner, and Weinberger (1989) argued that this lack of correlation should be taken seriously, and that as a minimum, psychologists should not call by the same name two measures which do not correlate with one another. They proposed that attitudinal or self-reported motives be referred to as *self-attributed* and the fantasy-derived motives be called *implicit* since a person is not explicitly describing him or herself as having the motive. These authors also recommended that motivation theorists consider the possibility that there are two qualitatively different kinds of human motivation, both of which are important. Compared to self-attributed motives, implicit motives are expected to be less cognitively elaborated, more often unconscious, and tied more closely to natural incentives and emotions.

There are three central differences in the way self-attributed and implicit motives relate to behaviour (McClelland et al., 1989). First, measures of implicit motives are thought to be more effective in predicting behaviour in relatively unconstrained situations whereas self-attributed motives, as measured in self-report inventories, more accurately predict attitudes and choices. Second, several studies have shown that the implicit motives tend to predict action trends over time better than the questionnaire measures. Finally, self-attributed and implicit motives appear to be particularly responsive to different classes of environmental incentives. Self-attributed motives are most likely to affect performance when there are relevant social incentives present in the situation. Thus, a person who reports being high in achievement motivation (i.e. high in self-attributed achievement motivation) is most likely to outperform someone who describes themselves as low in achievement when they are in a performance setting in which an authority figure stresses the importance of working hard and doing well. On the other hand, implicit motives as assessed by the fantasy method are primarily responsive to variations in the nature of task-inherent or activity-based incentives (Spangler, 1992).

There is evidence that a more comprehensive understanding of social motivation can be achieved by including measures of both self-attributed and implicit motives in research designs. The greatest amount of variance in behaviours, cognition, and affect are accounted for when both implicit and self-attributed measures of motives are assessed (McClelland et al., 1989; Woike, 1995).

AN ORGANISMIC CONCEPTION OF NEEDS AND A FOCUS ON SELF-REGULATION

The needs concept has various definitions across psychology, ranging from what one *wants* to what is *necessary* for one's psychological health and thriving (Ryan, 1995). Used in this latter, more exclusive sense, a need is a 'psychological nutriment' required for optimal health and thriving. That is, just as a plant requires water, sunlight, and good soil in order to grow, people require certain nutriments in order to be psychologically healthy and adapted. Deci and Ryan (2000) assume that there are three primary needs that all people must satisfy if they are to function well in life: the need for autonomy (i.e. freedom and choicefulness), the need for competence (i.e. felt efficacy), and the need for relatedness (i.e. connection to others). Recent research suggests that these needs may be universally important to people.

From this organismic perspective, the critical motivational issues concern whether one's goal pursuits provide the opportunity for satisfaction of the three intrinsic needs. The content of goals and various goal-related regulatory processes can be assessed with methods developed to measure personal strivings (Emmons, 1999). There is evidence that when the content of personal goals is congruent with the needs for autonomy, competence, and relatedness, people make greater progress and experience enhanced well-being (Sheldon, 2001). By contrast, pursuit of goals that are incongruent with intrinsic needs (e.g. pursuit of fame or popularity) has been associated with dysfunction even when progress has been made.

The process by which individuals regulate their goal pursuits will also importantly impact upon their success and well-being. Sheldon and colleagues have completed a series of short-term, prospective, longitudinal studies in which participants are asked to list several goals that they plan to strive for during the semester and then rate the goals in terms of autonomy (Sheldon, 2001). Autonomy is defined as the extent to which a goal reflects personal interests and values versus something one feels compelled to do by external or internal pressures. Specifically, participants are asked to rate four different reasons that range from highly controlled to highly autonomous. The four reasons for pursuing goals are external (i.e. 'because somebody else wants you to'), introjected (i.e. 'because you would feel ashamed, guilty, or anxious if you didn't'), identified (i.e. 'because you really believe that it is an important goal to have'), and intrinsic (i.e. 'because of the fun and enjoyment which the goal will provide'). Goal autonomy is calculated by combining the intrinsic and identified ratings and subtracting the introjected and external ratings. Autonomy and goal progress scores are aggregated across the various goals that

participants had set. Several recent studies revealed that individuals were significantly more likely to make successful progress when they had selected goals that were autonomous and that goal progress was systematically related to improved affect. The benefits of having autonomous goals were maintained after controlling for neuroticism and self-regulatory factors such as self-regulatory skill, goal efficacy, and goal commitment. The impact of autonomous goals on progress was shown to be mediated by the capacity to maintain sustained effort. That is, they appear to be protected and maintained in the face of task-irrelevant temptations because they are continually energized.

Several domain-specific scales of autonomous self-regulation have also been developed and validated. All of these scales ask respondents to consider their reasons for pursuing activities within a given domain such as school, sports, religion, or politics. For example, the Academic Motivation Scale was developed to assess individual differences in self-regulation toward high school or college (Vallerand, Fortier & Guay, 1997). Students are asked to rate the extent to which they go to school because of autonomous reasons (e.g. interest and personal importance) or for controlled reasons (e.g. external and introjected reasons). The scale is highly reliable and has shown considerable predictive validity. Thus, more autonomous students are less likely to drop out of school over time and report significantly higher levels of personal adjustment after completing school (Koestner & Losier, 2001).

A global scale of autonomous self-regulation, the General Causality Orientations Scale (GCOS), has also been widely used. It was constructed to be a general scale, one that cuts across domains and includes a wide range of responses and reactions (Deci & Ryan, 1985). The scales have demonstrated good internal and test–retest reliability and considerable predictive validity. The original validation studies conducted by Deci and Ryan (1985) showed that people's scores on the Autonomy scale of the GCOS were significantly positively related to measures of ego-development, self-esteem, and self-actualization. Subsequent research showed that autonomous individuals report focusing on enjoyment and challenge at work, rarely experience boredom, and explore within themselves when making a career choice (e.g. carefully weighing their own interests and abilities). Recent research has revealed that the autonomy orientation is associated with a high degree of integration in personality, a persistent approach toward one's goals, and experiencing greater intimacy and more positive emotions during everyday social interactions. These studies suggest that the global autonomy promotes goal pursuit and adaptive functioning (Koestner & Losier, 1996).

The extent to which goal pursuits are supported by robust competence beliefs has also been extensively explored. Albert Bandura (2001) assigned a central role to efficacy beliefs in determining whether particular goals will be pursued and achieved. 'Perceived self-efficacy' refers to judgements of how well one can perform actions required to deal with a prospective situation. Self-efficacy should not be confused with self-esteem (i.e. global evaluations of personal worth), it refers instead to capability beliefs regarding very specific actions. The assessment of self-efficacy beliefs therefore typically involves designing questionnaire items that inquire specifically about how confident one is that one can perform particular actions. It has been shown that such capability judgements predict performance independently of actual skill levels. There is considerable evidence that self-efficacy beliefs are associated with setting optimally challenging goals and persisting vigorously toward the completion of such goals. Furthermore, meta-analyses have confirmed the association of self-efficacy with positive work outcomes.

How people interpret their success or failure at goal pursuits also represents an important issue in motivation assessment because there is considerable evidence that performance attributions will influence persistence and future performance (Dweck, 1999). Performance attributions are typically assessed by asking people to rate the extent to which an outcome was determined by ability, effort, luck, or task difficulty (Weiner & Kukla, 1970). Research evidence suggests that attributions for success to ability factors is predictive of robust goal striving, but that ability attributions for failure promote helplessness (Weiner & Kukla, 1970).

FUTURE PERSPECTIVES AND CONCLUSIONS

Motivation researchers have shifted their focus from measuring the strength of relatively global individual differences in social motives such as the need for achievement or the need for power to the consideration of the extent to which self-regulatory processes support intrinsic needs such as autonomy and competence. The assessment of the strength of psychological needs such as achievement or power is most helpful in answering questions concerning why certain individuals are drawn to particular activities. The assessment of self-regulatory qualities such as autonomy and self-efficacy is most helpful in answering questions concerning why certain individuals are successful at reaching their personal goals, and whether such success will translate into enhanced adjustment. A full understanding of the pattern and flow of human behaviour and experience thus will require attention to both social motives that are instrumental in selecting goals and to the self-regulatory processes that sustain goal striving.

MOTOR SKILLS IN WORK SETTINGS

INTRODUCTION

Despite the fact that work is increasingly mechanized and automatized, motor skills are still the main vehicles by which tasks in industrial settings are performed. The literature in this area is vast, originating from psychology, engineering, biology, neuroscience, kinesiology, and physical education. Within the present limited framework, only a few topics can be dealt with to provide some understanding of the basic concepts and a flavour for the field.

First some classificatory schemas and definitions will be provided, and a brief overview is given of the major motor control theories. Then a short description of how movement speed and movement accuracy is formalized in Fitts' law is followed by some methods of observation applied in work settings.

MOTOR SKILLS

A motor skill is defined by Jensen, Schulz, and Bangerter (1983) as the ability to use the correct muscles with the exact force necessary to perform the desired response with proper sequence and timing. Some conceive motor skill also as the capacity to adapt to changing environmental conditions and the consistency of action across repetitions; this is called motor equivalence (Rosenbaum, 1991).

TYPES OF MOVEMENT CLASSIFICATIONS

Capturing the wide repertoire of physical activities requires some ordering principles. A frequently applied classification distinguishes discrete, serial, and continuous movements (e.g. Sanders & McCormick, 1993; Schmidt, 1988). *Discrete* movements involve a single aiming movement to a stationary target with a clearly defined start and end, such as reaching for a control knob or pointing to a command field on a computer display. *Serial* movements involve a series of discrete movements. When similar discrete movements are repeated, like tapping a cursor key on a keyboard or hammering on a nail, they are mostly called repetitive movements, while the term sequential movements applies to a series of discrete movements carried out to a number of stationary targets that are regularly or irregularly spaced, e.g. playing the piano, typewriting, or reaching for parts in various stock bins. *Continuous* movements refer to a class of movements of which the beginning and the end must be arbitrarily defined, as with swimming and steering a car. An additional distinguishing

feature is that these movements need muscular control adjustments during the movement, as in guiding a piece of fabric through a sewing machine. Though not strictly a movement, maintaining posture or a *static* positioning for a period of time might be considered as an additional movement class.

Assessment of motor skills in work settings can be approached also from a *process* perspective: the preparation and execution processes involved in motor skills. In that case one describes motor skills, respectively, in terms of the involved information processes and the cognitive load emerging from preparatory and controlling demands, as well as in terms of maintaining the spatio-temporal trajectory, speed or force of the movement. Another level of description concerns the *quality* of movement outcome, both in qualitative (jerky, good) and quantitative (numbers expressing spatial accuracy, produced force) measures. A last classification schema addresses the predictability of the environment: a movement might belong to the class of open skills (football, soccer) or closed skills (darting, most machine operating skills).

THEORIES ON MOVEMENT CONTROL

The two basic theories of movement control are closed-loop and open-loop models. Central to open-loop models is the concept of a central representation commonly called the motor program. A *motor program* may be viewed 'as a set of muscle commands that are structured before a movement sequence begins, and allows the entire sequence to be carried out uninfluenced by peripheral feedback' (Keele, 1968: 387). Programming demands of a movement skill might be indexed by reaction time or preparation time. Preparation time can be shortened by providing relevant movement information in advance or storing the required movement program as a whole, i.e. by locking prespecified parameter values into the program as a result of learning. It is generally assumed that a class of movements is controlled by a generalized motor programme containing a set of parameters (e.g. relative timing and sequencing of movements) that are provided with specific values for each individual movement of that class to tailor the response to the situation.

Closed-loop theories stress the sensory information signals as the main control agent for movements. Movement control is exerted by comparing the effect of the action to some representation of what the action should be. Any discrepancy is considered error and, as in a negative feedback system, the movement is adjusted to reduce the error. Closed-loop theories may be adequate to explain the control of slow movements, but have problems in explaining fast movements, because in that case time for processing the error-signal might be too short though response-adjustment times of less than 100 ms for an object slipping out of hand or of about 150–200 ms for visually based movement corrections are reported.

A hybrid or intermittent mode of control, where programmed sequences are coordinated and monitored allowing feedback-based adjustments during movement execution, is the usual type of control, for instance the arm-transport phase and a prehension phase which must be coordinated in reaching for a tool. The fine-tuning of open-loop and closed-loop controlled movement execution processes reflects the proficiency of the motor skill. Increasing the proficiency of a movement skill mostly involves also the piecing together of various programmed units into one integrated general structure making it more resistant to change.

SPEED–ACCURACY RELATION

The distance to be covered by the movement and the precision demanded by the size of the target to which one is moving affects the time to exert the movement. An important relation between movement accuracy and movement speed was found by Fitts (1954). He discovered that movement time was a logarithmic function of distance (target size) when target size (distance) was held constant, now called Fitts' law: $MT = a + b \log_2(2D/W)$, in which MT is movement time, a and b are empirically derived constants depending on the type of movement involved, D is the distance of movement from start to target centre and W is the width of the target.

An excellent overview on theories and research of motor skills, like motor learning, reaching and grasping, catching, writing and drawing, posture,

walking, etc., can be found in a comprehensive handbook (Heuer & Keele, 1996).

MEASUREMENT AND OBSERVATION METHODS

Movement skills can be measured on different levels (see previous paragraph) and from different disciplines, such as medicine, sport, kinesiology, vocational rehabilitation, psychology (experimental, developmental), ergonomics, and many more. Some instruments for recording [changes in] postures and basic motor skills in a work setting will be described.

Posture Description

In work settings postures in relation to their contribution to discomfort, strain, stability, or force exertions can be assessed by subjective scoring by workers themselves (e.g. Borg's scale; Nordic Questionnaire) and by observation with the help of standard forms and formulas (e.g. NIOSH-method, OWAS-method, RULA) or with computerized recording (e.g. TRAC-method, Workman-1 method, Owasco & Owasan-method). The instruments can be used for recording work posture and physical load during lifting situations, if a wider margin of error is acceptable. Application mostly requires training (e.g. see Wilson & Corlett, 1999, for an overview).

Indirect observation of body motions is possible through methods which use one, two, or more video cameras to track passive or active markers on a moving subject that can be analysed off-line. Some commercially available systems are CODA, Elite, Optotrak, Proreflex, Vicon, Watsmart, and MotionStar (based on magnetic-induction principle).

Body motions can also be recorded directly. Individual angles between adjacent body segments can be measured using a simple goniometer. By the use of flexible strain-gauges, which are strapped to the joint, recording of motion over a period of time is possible. Range of Movement (ROM) describes the amount of movement, expressed in degrees, through a particular plane that occurs in a joint. A rough measure of tolerable static effort can be derived from lifting and holding times for various loads, expressed as a proportion of maximum voluntary contraction. Electromyography is a good technique for assessing which muscles are used in a task but is of more limited use in accurately assessing the fatigue process.

Simple Motor Tests

A variety of motor skills diagnosis and training instruments is available based on simple movement tasks, like aiming, paced and unpaced tapping, tracing and pursuit tracking, performed unimanually or bimanually. The objective of these instruments is to assess fine motor skills, like speed of arm/hand movement, eye–hand coordination, finger–hand steadiness, bimanual coordination. They are mostly based on standard paradigms of experimental psychology, are objective, reliable and have a high content and logical validity, some of them even provide norm values. Temporal and spatial accuracy, coordination proficiency, and speed are the main dependent variables. Application domains are specific tasks in industry, traffic, and the military. Most of these tests are commercially available as (parts of) psychomotor testing systems (e.g. Vienna Testing System).

In the field of vocational rehabilitation various assessment systems for motor skills exist. A very comprehensive system is Ergos, for example. It consists of five units measuring different aspects of potential body movements: static and dynamic force, whole body range of motion, work endurance, standing and walking, and sitting and reaching. During a 5 hour session, 42 parameters are assessed and compared to more than 14,000 job descriptions.

FUTURE PERSPECTIVES AND CONCLUSIONS

Most measurement devices, tests, and instruments for assessing motor skills provide objective and reliable data which mainly are predictive for performance of a specific movement type or in a narrow set of tasks. Only a few provide norm tables. They emanated from paradigms with which in applied and experimental psychology motor control has been studied suggesting a high content validity. Generally the recording devices possess a high temporal and spatial accuracy.

Computer work increases the risks of Repetitive Strain Injury (RSI) or Cumulative Trauma Disorder (CTD), hence appropriate motor skill tests are required. Furthermore, there is still need for norm tables and prognostic validity of many current motor skill tests.

MULTIDIMENSIONAL ITEM RESPONSE THEORY

Item response theory (IRT) models are stochastic models for responses of persons to items, where the influences of items and persons on the responses are modelled by disjunctive sets of parameters. In the framework of educational and psychological measurement, the person parameter can usually be labelled ability or proficiency; in the sequel, the term ability will be used. The definition of separate parameters for persons and items supports a comprehensive framework for many important issues in educational and psychological measurement, such as test scoring, validity, local reliability, test equating, calibration of item banks using incomplete designs, differential item functioning, optimal test construction and computerized adaptive testing (see, for instance, Lord, 1980, or Hambleton & Swaminathan, 1985).

In many instances, it suffices to assume that ability is unidimensional. However, in other instances, it may be a priori clear that multiple abilities are involved in producing the manifest responses, or the dimensionality of the ability structure might not be clear at all. In such cases, multidimensional IRT (MIRT) models can serve confirmatory and explorative purposes, respectively. As this terminology suggests, many MIRT models are closely related to factor analytic models; in fact, Takane and de Leeuw (1987) have identified a class of MIRT models that is equivalent to a factor analysis model for categorical data. This class of models will be treated first. Then attention will be given to a second class of MIRT models, defined by the existence of minimal sufficient statistics and closely related to loglinear models for the analysis of discrete data. This entry will be concluded with some remarks about the choice between the two models.

In the first class of models, MIRT models for dichotomously scored items were first presented by McDonald (1967) and Lord and Novick

(1968). These authors use a normal ogive to describe the probability of a correct response. The idea of this approach is that the dichotomous response of person i to item j is determined by an unobservable continuous random variable. This random variable has a standard normal distribution and the probability of a correct response is equal to the probability mass below some cut-off point η_{ij}. That is, the probability of a correct response is given by

$$p_{ij} = \Phi(\eta_{ij}) = \Phi\left(\sum_{q=1}^{Q} \alpha_{jq}\theta_{iq} - \beta_j\right),$$

where $\Phi(.)$ is the cumulative standard normal distribution, θ_{iq}, $q = 1, \ldots, Q$, are the Q ability parameters (or factor scores) of person i, β_j is the difficulty of item j, and α_{jq}, $q = 1, \ldots, Q$, are Q factor loadings expressing the relative importance of the Q ability dimensions for giving a correct response to item j. Further, it is assumed that the ability parameters θ_{iq}, $q = 1, \ldots, Q$, have a Q-variate normal distribution with a mean-vector μ with the elements μ_q, $q = 1, \ldots, Q$, and a covariance matrix Σ. So it is assumed that Q ability dimensions play a role in test response behaviour, the relative importance of these ability dimensions in the responses to specific items is modelled by item-specific loadings α_{jq}, and the relation between the ability dimensions in some populations of respondents is modelled by the correlation between the ability dimensions.

For the analysis of responses to multiple-choice items, the model can be extended to

$$p_{ij} = \gamma_j + (1 - \gamma_j)\Phi(\eta_{ij})$$

by introducing a guessing parameter γj. A comparable model using a logistic rather than a normal-ogive representation has been proposed by Reckase (1985, 1997) and Ackerman (1996a & b).

Restrictions have to be imposed on the parameters to identify the model. One approach to identify the model is setting the mean and the covariance matrix equal to zero and the identity matrix, respectively, and introducing the constraints $\alpha_{jq} = 0$, $j = 1, \ldots, Q - 1$ and $q = j + 1, \ldots, Q$. So, here the latent ability dimensions are independent and it is assumed that the first item loads on the first dimension only, the second item loads on the first two dimensions only, and so on, until item $Q - 1$, which loads on the first $Q - 1$ dimensions. All other items load on all dimensions.

An alternative approach to identifying the model is setting the mean equal to zero, considering the covariance parameters of proficiency distribution as unknown estimands. The model is then further identified by imposing the restrictions, $\alpha_{jq} = 1$, if $j = q$, and $\alpha_{jq} = 0$, if $j \neq q$, for $j = 1, \ldots, Q$ and $q = 1, \ldots, Q$. So, here the first item defines the first dimension, the second item defines the second dimension, and so forth, until item Q which defines the Qth dimension. Further, the covariance matrix Σ describes the relation between the thus defined latent dimensions.

In general, however, these identification restrictions will be of little help to provide an interpretation of the ability dimensions. Therefore, as in an exploratory factor analysis, the factor solution is usually visually or analytically rotated. Often, the rotation scheme is devised to approximate Thurstone's simple-structure criterion (Thurstone, 1947), where the factor loadings are split into two groups, the elements of the one tending to zero and the elements of the other toward unity.

As an alternative, several authors (Glas, 1992; Adams & Wilson, 1996; Adams, Wilson & Wang, 1997; and Béguin & Glas, 2001) suggest identifying the dimensions with subscales of items loading on one dimension only. The idea is to either identify these $S < Q$ subscales a priori in a confirmatory mode, or to identify them using an iterative search. The search starts with fitting a unidimensional IRT model by discarding non-fitting items. Then, in the set of discarded items, items that form a second unidimensional IRT scale are identified, and this process is repeated until S subscales are formed. Finally, the covariance matrix Σ between the latent dimensions is estimated either by imputing the item parameters found in the search for subscales, or concurrently with the item parameters leaving the subscales intact.

Several methods have been proposed to estimate the model. The first approach is to use a two-step procedure where the first step consists of estimating the covariance matrix of the latent variables using tetrachoric correlations and the second step consists of factor analysing this

matrix using standard software (LISREL, Jöreskog & Sörbom, 1996; EQS, Bentler, 1992; LISCOMP, Muthén, 1987). A second approach, developed by McDonald (1967, 1982, 1997), is based on an expression for the association between pairs of items derived from a polynomial expansion of the normal ogive. The procedure is implemented in NOHARM (Normal-Ogive Harmonic Analysis Robust Method, Fraser, 1988). The third approach, using all information in the data, and therefore labelled 'Full Information Factor Analysis', was developed by Bock, Gibbons, and Muraki (1988). This approach is a generalization of the marginal maximum likelihood (MML) estimation procedure for unidimensional IRT models (see Bock & Aitkin, 1981), and has been implemented in TESTFACT (Wilson, Wood & Gibbons, 1991). MML estimates for MIRT models with subscales can be obtained using CONQUEST (Wu, Adams & Wilson, 1997). Finally, fully Bayesian approaches with computational methods based on the Gibbs sampler were proposed by Shi and Lee (1998) and Béguin and Glas (2001). For an overview of the relative merits of the various procedures refer to the latter two articles.

The MIRT model for dichotomous items is generalized to a model for polytomous items with m_j ordered response categories by assuming m_j standard normal random variables, and m_j cut-off points η_{ijk} for $k = 1, \ldots, m_j$. The probability that the response is in category k is given by

$$p_{ijk} = \Phi(\eta_{ij(k-1)}) - \Phi(\eta_{ijk}),$$

where $\eta_{ijk} = \sum_{q=1}^{Q} \alpha_{jq}\theta_{iq} - \beta_{jk}$, $\eta_{ij(k-1)} > \eta_{ijk}$, $\eta_{ij0} = \infty$, and $\eta_{ijm_j} = -\infty$. Takane and de Leeuw (1987) point out that also this model is both equivalent to an MIRT model for graded scores (Samejima, 1969) and a factor analysis model for ordered categorical data (Muthén, 1984). This model can be estimated using standard software for factor analysis (see previous paragraph) or using a fully Bayesian approach (Shi & Lee, 1998).

Attention will now be focused to a second class of MIRT models, which is defined by the existence of minimal sufficient statistics and closely related to loglinear models for the analysis of discrete data. The model was probably first proposed by Rasch (1961), and worked out in detail by Fischer (1974), Kelderman (1984, 1989, 1997), Kelderman and Rijkes (1994), and Agresti (1993). The general formulation of the model is given by

$$p_{ijk} = \exp\left[\sum_{q=1}^{Q} \alpha_{jkq}\theta_{iq} - \beta_{jk}\right] h_{ij},$$

where h_{ij} is a normalizing constant that depends on the parameters but is constant for all response categories. There are two important differences between the present model and the loglinear formulation of the factor-analytic MIRT model (Reckase, 1985). Firstly, the α_{jkq}-parameters are now known integers which play a role as minimal sufficient statistics for the ability parameters. For that reason they will be called scoring-weights. Secondly, no assumptions are made about the distribution of the ability parameters. In fact, the item parameters β_{jk} can be estimated by conditional maximum likelihood (CML), which is based on a likelihood where the person parameters θ_{iq} are removed by conditioning on their sufficient statistics. The estimates can be computed using LOGIMO (Kelderman & Steen, 1988). Special cases of the model can be derived by fixing specific scoring-weights; for an overview refer to Kelderman (1997). Further, Kelderman points out that special models for specific hypotheses about the response process can be modelled by choosing the scoring-weights. That is, the relative weight of an ability dimension for producing a response in some category can be reflected in the choice of the scoring-weights. A zero value is chosen when it is assumed that the specific ability dimension does not play a role for this specific category or item.

CONCLUSIONS

The final remark pertains to the choice of an MIRT model. Although this choice is not always clear-cut, the following observations can be made. Firstly, in the loglinear model the score weights are fixed. Therefore, it is a much more restrictive model than the factor-analysis model. Further, the tools for statistical testing are more sophisticated in the loglinear model. Therefore, one might argue that the loglinear approach can play an important role in test construction in situations where items pertaining to some psychological construct can be

selected from some pool of potential items. This situation is characterized by a focus on a theoretical framework and validity issues. The factor-analytic approach is more appropriate for exploring the structure of some item pool in the absence of an elaborate theoretical framework or in situations, such as in educational measurement, where the item pool is created following the specifications of content matter experts and an appropriate model must be found to describe the data as they come.

Item Response Theory: Models and Features, Factor Analysis: Confirmatory, Multidimensional Scaling Methods

MULTIDIMENSIONAL SCALING METHODS

INTRODUCTION

The verb *to scale* means 'to arrange in a graduated series' (Webster's, 1961). Multidimensional scaling means arranging people (or objects) in two or more graduated series. A personality inventory may measure adults on their extroversion and conventionalism, thus yielding two graduated series: extroversion and conventionalism. Each graduated series is a *dimension*. Hence the term multidimensional scaling.

A *scaling model* is a statistical function expressing the relationship between location on a psychological dimension, X, and a behavioural response $B : B = \mathrm{f}(X)$. The dimension might be psychological extroversion. The behaviour might involve reacting to the statement 'I like loud parties' by choosing one of two responses: 'True of me'; or 'Not true of me'. The scaling model would express the probability of choosing the response 'True of me' as a function of extroversion.

If a good scaling model can be found, dimension X can be measured by observing the behaviour and then computing $X : X = \mathrm{f}^{-1}(B)$. The score X then constitutes our measurement. When the behaviour is a response to a test item, then the scaling model is called an item response theory (see entry on 'Items Response Theory: Models and Features').

If the behaviour is a function of two or more dimensions, the scaling model is said to be multidimensional. $\mathbf{B}$ becomes a vector of behaviours and $\mathbf{X}$ becomes a vector of measurements along two or more dimensions. After observing the several behaviours in vector $\mathbf{B}$, the measurements along the dimensions can be taken by computing $\mathbf{X} = \mathrm{f}^{-1}(\mathbf{B})$.

Multidimensional assessment methods fall into two categories, semi- and fully multidimensional. Fully multidimensional assessments are multidimensional in three respects. First, they employ complex tasks, each of which is a function of more than one dimension. Second, they employ multidimensional scaling models. Third, they yield a description of people (or objects) along two or more dimensions. Semi-multidimensional methods are multidimensional only in the last of these three respects. In what follows, semi- and fully multidimensional methods are discussed. Within the semi- and fully multidimensional sections, methods designed primarily for measuring attributes of people and methods for measuring perceptions of stimuli are considered separately.

SEMI-MULTIDIMENSIONAL METHODS

Tests Measuring Individual Differences

A semi-multidimensional technique derives a multidimensional measurement of a person (or object) from multiple, unidimensional behaviours. Imagine a test battery containing reading and mathematics items. B_1 and B_2 are responses to reading items; B_3 and B_4 are responses to the

mathematics items. Let X_R and X_M be variables representing the reading and mathematics achievement dimensions. In a semi-multidimensional technique, it might be assumed that $B_1 = f_1(X_R)$, $B_2 = f_2(X_R)$, $B_3 = f_3(X_M)$, and $B_4 = f_4(X_M)$. The set of behaviours measuring reading and the set of responses measuring mathematics are mutually exclusive sets. Because the responses and the scaling model are unidimensional, the method is only semi-multidimensional even though it yields reading and mathematics scores.

Many cognitive and achievement test batteries called 'multidimensional' are, in fact, semi-multidimensional, because they employ several sets of unidimensional test items that, in combination, form a multidimensional description of the test taker.

Measuring Perceptions of Stimuli

Multiattribute scaling is a term sometimes used to describe semi-multidimensional methods for assessing perceptions of stimuli (Ward & Newman, 1982; Baird & Noma, 1978). In multiattribute scaling, the psychologist begins by delineating the stimulus dimensions to be measured. A marketing researcher studying pizzas might list three dimensions: taste, texture, and appearance. The researcher might ask pizza consumers to rate taste, texture, and appearance on 5-point scales where 1 = very unappealing and 5 = very appealing. Taken together, these three unidimensional ratings of taste, texture, and appearance would constitute a semi-multidimensional description of the pizzas.

Semi-multidimensional approaches make two assumptions, assumptions that are not always tenable. First, they assume the psychologist can list the relevant dimensions. In some cases, these are not known with certainty. In other instances, the salient dimensions vary across people. Secondly, they assume that the psychologist can devise suitable unidimensional response tasks. Such tasks may not be available, or dimensionally complex tasks may be more suitable.

FULLY MULTIDIMENSIONAL METHODS

Tests Measuring Individual Differences

Multidimensional scaling models for items have only begun to emerge even though multidimensional item responses have always existed. Story problems on mathematics tests require both reading and writing ability. Portfolio and work performance assessment (see entry on 'Performance') utilize complex tasks tapping multiple abilities.

Rudimentary fully multidimensional approaches have long existed in the assessment of interests and personality: e.g. the *Minnesota Multiphasic Personality Inventory*, the *California Personality Inventory*, and the *Strong Vocational Interest Blank* (Butcher et al., 1989; Gough, 1987; Hansen & Campbell, 1985). In any test or inventory on which items are keyed to more than one subscale, items are implicitly assumed to be multidimensional. An item asking about interest in reading computer manuals might reflect two interest dimensions, an interest in computers and an interest in technical writing. If so, the item would be keyed to a subscale entitled 'Interest in Computer Science' and one entitled 'Interest in Technical Writing'.

Fully multidimensional models for tests and questionnaires are covered in the entry on 'Multidimensional Item Response Theory'.

Measuring Perceptions of Stimuli

Semi-multidimensional approaches assume that, if the respondent is told to make a judgement based on only one attribute of an object, the respondent will ignore extraneous attributes. There is ample evidence to the contrary (Clark & Lawless, 1994). In personnel evaluation (see entry on 'Personel Selection, Assessment in'), one explanation for the 'halo effect' is that supervisors cannot separate their global impression of an employee from their evaluation on a specific dimension. In fully multidimensional approaches, the respondent makes an overall judgement about the stimulus from which measurements along each separate dimension are derived in a subsequent analysis.

In the approach using *preference judgements* (Bechtel, 1976), the respondent is shown a single object (e.g. a pizza) and asked to make an evaluation of the object, usually on a rating scale (single stimulus approach), or the respondent is shown a pair of objects and asked to indicate which object they prefer and by how much (paired comparison approach). In either approach, the respondents base their judgements on an overall evaluation of the object(s) and presumably consider

several attributes rather than one specific attribute (Green & Wind, 1973).

The major scaling models for preference data have been based on linear or distance assumptions. According to the linear model for a single stimulus judgement, either the behaviour or a monotone transformation of it, $_T(B_{sr})$, is assumed linearly related to scale values:

$$B_{sr} = \sum_d W_{rd} X_{sd} + a_r \tag{1a}$$

or

$$_T(B_{sr}) = \sum_d W_{rd} X_{sd} + a_r. \tag{1b}$$

The latter is called a non-metric model. Here B_{sr} is the response of respondent r to stimulus s, X_{sd} is the measurement of stimulus s on dimension d, W_{rd} is a weight reflecting the salience of dimension d to the behaviour of respondent r, and a_r is an additive constant unique to respondent r. The scaling algorithm uses the responses as input to solve for the parameters in the model, including the measurements X_{sd}. The weight estimates W_{rd} describe individual differences in the saliences of dimensions to respondents.

According to the distance model, a stimulus is highly evaluated to the extent that it matches an ideal, represented in the model by a set of coordinates Y_{rd}. That is, the behaviour is assumed inversely related to the squared difference between the location of the stimulus and the location of the ideal point for respondent r along each dimension:

$$B_{sr} = a - \sum_d (X_{sd} - Y_{rd})^2 \tag{2a}$$

or

$$_T(B_{sr}) = a - \sum_d (X_{sd} - Y_{rd})^2. \tag{2b}$$

Given the responses, the scaling algorithm will solve for estimates of the parameters in the model, including the stimulus measurements X_{sd}. The estimates of Y_{rd} constitute a description of the ideal point for respondent r.

In the approach using *similarity judgements*, the respondent is shown a pair of stimuli and asked to judge the (dis)similarity of the objects. The most well-known methods are based on distance assumptions. The greater the dissimilarity between two objects, the farther apart they are assumed to be in a Euclidean space:

$$B_{ss'} = \sum_d (X_{sd} - X_{s'd})^2 \tag{3a}$$

or

$$_T(B_{ss'}) = \sum_d (X_{sd} - X_{s'd})^2. \tag{3b}$$

Here $B_{ss'}$ is the judged dissimilarity between stimuli s and s' and X_{sd}, $X_{s'd}$ are the measurements of stimuli s and s' along dimension d. Given the responses, the scaling algorithm will solve for estimates of the parameters in the model, the measurements X_{sd}. If there are individual differences in the saliences of dimensions, subject weights can be incorporated into the model to reflect those individual differences.

Figure 1 shows a three dimensional representation from a person perception study by Jones and Young (1972). The stimuli were 17 members of an academic unit (professors and students). Respondents judged the similarity of all possible pairs of members. The authors concluded that there were three dimensions underlying the similarity judgements, political persuasion (liberal vs. conservative), status, and professional interest (statisticians vs. substantive researchers). The algorithm yielded a set of three measurements (scale values) for each member, one locating that member along the political persuasion dimension, one locating that member along the status dimension, and one locating that member along the professional interests dimension (Figure 1).

In fully multidimensional approaches, two problems arise. First, the researcher does not specify the number or nature of the attributes to be considered by respondents in making their judgements. The number of dimensions and the nature of the dimensions must be determined based on the scaling results. Second, with some exceptions, solutions are determined only up to a rotation, translation of axes, and uniform stretching or shrinking of all axes. Sources such as Davison, (1992); Davison and Sireci, (2000); and Borg and Groenen, (1997) discuss a number of dimensions, dimension interpretation, and solution uniqueness.

While multidimensional scaling methods based on distance models were designed for the analysis

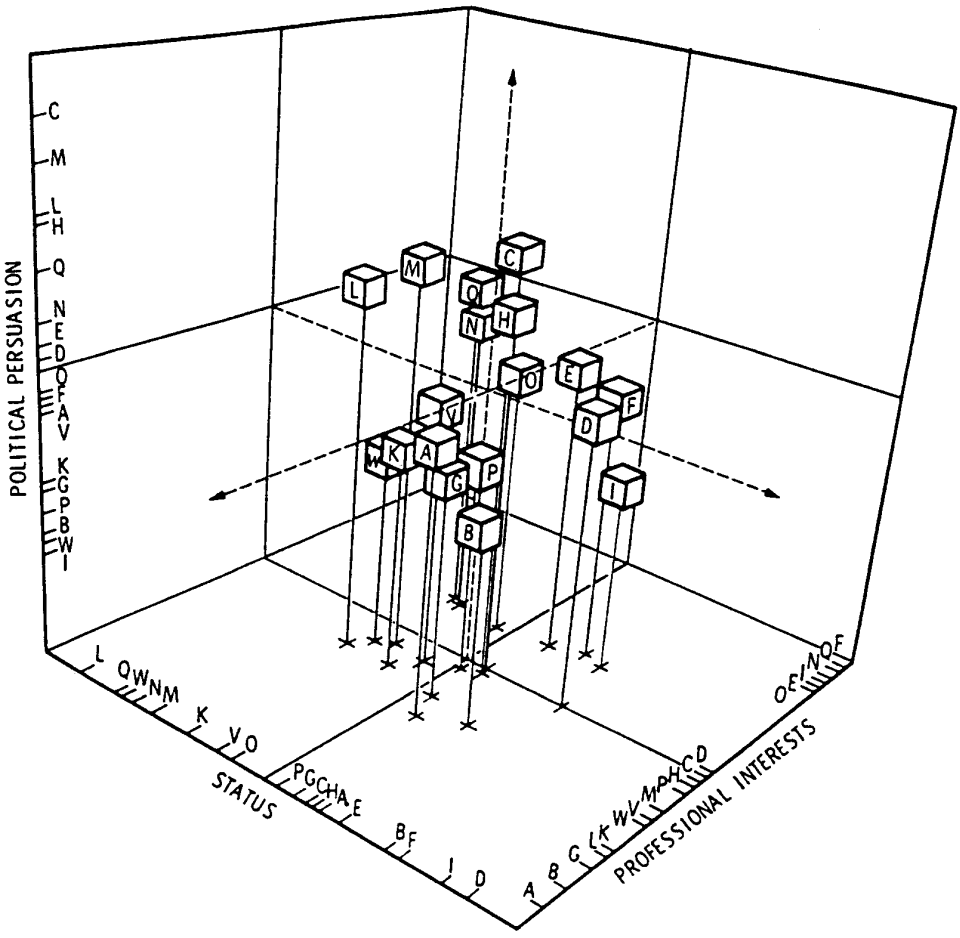

Figure 1. Stimuli coordinate space. The letters A–I denote faculty and a postdoctoral fellow. Letters K–Q, V and W denote graduate students. Copyright 1972 by the American Psychological Association.

of similarity judgements, they have also been used to study a number of issues in testing and assessment, including the dimensionality of a set of items, the most prominent profile patterns in batteries of test scores, and content validity (Davison & Sireci, 2000).

FUTURE PERSPECTIVES AND CONCLUSIONS

Currently, assessments labelled multidimensional often are not fully multidimensional. Fully multidimensional item response models will see wide application after a period of research and development. Fully multidimensional models for perceptual data have seen more application, particularly in marketing research. Ultimately, multidimensional models will make their greatest contribution by expanding the set of complex tasks that can be used for measurement purposes, and thereby open the way for a new generation of tests and assessments.

MULTIMODAL ASSESSMENT (INCLUDING TRIANGULATION)

INTRODUCTION

The aim of this entry is to give a short introduction to the basic concept of multimodal assessment. It deals with the definition of the concept and its differentiation from other concepts, points out the relevance of the strategy in research and practice, emphasizes the main aspects and gives some examples of application in the field of clinical psychology and psychotherapy. Finally, some proposals for future developments are given.

DEFINITIONS

It is generally agreed that human behaviour and experience have to be recorded in a *multimodal* way (other terms occasionally used: multimethod, multimethodically). Thus, distinctions are made between the following aspects (Baumann et al., 1985): databases, sources of data and functional ranges (see Table 1).

On occasions another aspect is added: the type of instruments which are used to assess the relevant aspects of interest (e.g. rating scales, achievement tests, technical procedures).

A term with a similar meaning is *multiaxial* classification, which is used in psychiatry and clinical psychology. This involves describing the patient on different axes or dimensions with the aim of structuring information (about the patient), in order to obtain a more adequate representation of the complexity of the clinical picture and to gather information about the

Table 1. Multimodal assessment

Databases	Basic units of consideration (perspectives: e.g. biochemical, physiological, psychological, social, ecological)
Sources of data	Data provider (e.g. patient, therapist, nursing staff, reference person, neutral observer)
Functional ranges	Partial aspect within a database (e.g. psychological databases: experiences, behaviour, feeling, working capacity)

patient which is relevant to treatment. In general, the following axes (not to be confused with axes or dimensions in factor analyses) are distinguished: clinical syndromes, disabilities/global assessment of functioning or environmental/circumstantial factors.

RELEVANCE

Multimodal assessment can be understood as a *general framework* which has to be specified for the concrete assessment of individual persons or groups of persons, making it necessary to select specific instruments. The choice should be made according to specific criteria. On the one hand, methodological aspects should play a central role (e.g. high psychometric quality, especially reliability and validity). At the same time conceptual considerations should be of equal relevance. This means instruments should be used which allow the characterization of the important aspects of the construct in question.

A multimodal approach is generally required for evaluation, e.g., of psychotherapy and psychotropic drugs research in order to cope with the complexity of the phenomena studied. Multimodal assessment in this area is increasingly gaining importance because of the range of competing psychotherapeutic methods, the development of disturbance-specific treatment approaches as well as manualized/standardized therapy approaches. It is necessary to choose a multimodal approach in order to do justice to the complexity of this area and to account for the variance as to the degree of exactness in databases and data providers as well as functional ranges.

Furthermore, the necessity of a multimodal approach arises from the need to reduce investigator-dependent rating bias and results in the inclusion of different perspectives. With regard to the self-rating scales, bias may include acquiescence, central tendency, or social desirability, on the level of observer-rating scales it may come from insufficient experience with the scale, response sets like generosity error or error of leniency. In planning a study, care has to be taken that it contains sufficient distinct measures to cover the domain of interest, but also that it does not include redundant measures (reduction of statistical power).

PARTICULAR ASPECTS OF MULTIMODAL ASSESSMENT

Relation between Self- and Observer-Rating Scales

In clinical psychology and psychotherapy, where there are usually different data providers for the psychological database (with the patient and the therapist as the most important sources), the relation of self-rating and rating by observers is of particular importance. Both are characterized in relation to other assessment methods in that they are applicable in a vast range of areas and that they are easy to administer (e.g. time-saving).

There are various ways of clarifying the relation between both assessment strategies (e.g. Baumann et al., 1985):

- Assessment of the same facts using the same method by patient and rater,
- Assessment of the same facts using different methods (e.g. self-rating by items and resulting scale values versus rating by others using a global rating scale),
- Structural comparisons of data obtained by observer- and self-rating scales (i.e. factors analysis) or other complex procedures like the multi-trait, multi-method analysis (*cf.* entry on 'Multitrait–Multimethod Matrices' in this volume),
- Comparison of the statements obtained from observer-rating and self-rating scales (e.g. determination of effect sizes).

There is extensive literature available which compares both strategies, especially in the area of psychotherapy and psychopharmacotherapy. Independent of the analysed groups of disorders the results of the studies converge. The following conclusions can be drawn in relation to both strategies:

- Both groups of instruments only correlate to a medium degree.
- Observer-rating scales provide a better differentiation between groups of patients than self-rating scales.
- Observer-rating scales are more sensitive in detecting differences between groups of patients than self-rating scales.
- Great discrepancies are often observed on the level of individual patients.

Various factors may account for these discrepancies:

- The instruments cover different aspects of the construct of interest (e.g. the different instruments used to assess the depressive syndrome),
- The perspective of the patient him- or herself and other data sources are different.

In summary, this does not mean that observer-rating scales are generally to be preferred to self-rating scales. Because not all phenomena of interest (e.g. mood, feelings, complaints) can be assessed with observer-rating scales, they therefore complement each other.

Concordance/Discordance and Synchronicity/Desynchronicity

The question of the degree to which the different databases and data providers correspond has aroused particular interest. If different parameters are identical at the same time, it is referred to as *concordance*, if they are not, this is referred to as *discordance*. If there is a correlation of two depression rating scales in the range of 0.80, convergence can be assumed. If the correlation is 0.50, this is no longer the case, i.e. both instruments cover different aspects of the syndrome (only 25% common variance). If the course of different parameters are parallel over time, there is *synchronicity* (e.g. parallel changes of cognitions and somatic symptoms during anxiety therapy), if not, there is *desynchronicity* (e.g. reduction of avoidance behaviour in the continuing presence of negative cognitions). Each case of discordance or desynchronicity requires an explanation, in clinical routine as well as in research.

In various studies, it was shown that convergence was rather low at the beginning of the therapy and then increased during the course of treatment, reaching its highest point at the end of the therapy (e.g. Möller, 1991).

Triangulation

A term often used in the context of multimodal assessment is triangulation. The concept was developed to find out if a hypothesis was correct when confronted with complementary assessment instruments (Flick, 1991; methodological strategy: multitrait–multimethod analyses).

The term triangulation is used in different ways. According to Green and McClintock (1985) it has a similar meaning as mentioned above (use of two or more different methods to measure the same phenomenon). The goal of triangulation is to strengthen the overall findings through congruence and/or complementarity of the results from different methods. Congruence here means similarity, consistency, or convergence of results, whereas complementarity refers to one set of results enriching, expending upon, clarifying, or illustrating the other. Therefore, triangulation is intended to serve two distinct purposes: confirmation and completeness. The aim of triangulation is not to achieve complete agreement, but to demonstrate the strength and weakness of the single analysis and to integrate the results into a picture.

In an extended meaning of the word, triangulation stands for the *integration of qualitative and quantitative strategies*. According to Kay et al. (1993), evaluation of a course of treatment needs to be approached at several levels. A quantitative level analysis aims to aggregate material, such as the measurement instruments. It may show whether the treatment has an effect on a group, and to what degree it is effective. The qualitative analysis of outsider and insider evaluations could be, for example, the perceived satisfaction of patients and their family members. By analysing individual-level qualitative data it is possible to learn in some ways how and why the treatment achieved the efficacy and satisfaction level reported.

EXAMPLE

For most psychiatric disorders, a multimodal approach is necessary for an adequate description because a gold standard is missing. An example is presented in Table 2. Anxiety disorders in particular are characterized as disorders with different components such as subjective experiences, specific behavioural reactions, and a broad spectrum of somatic/vegetative symptoms.

Table 2. Multimodal assessment of anxiety disorders (examples)

Databases	Psychological, physiological, social
Sources of data	patient, therapist, independent/trained rater, relevant others (e.g. family members)
Functional ranges	• Psychological database: cognitions, emotional reactions, behaviour • Physiological database: physiological reactions • Social database: impairments and handicaps, social support
Assessment instruments	Self- and observer-rating scales, structured or standardized interviews, diaries, behaviour observations, behavioural tests, self-monitoring, physiological assessment instruments

Depending on the specific aim of a study (e.g. the natural course, efficacy of a therapeutic intervention), a broad range of aspects have to be considered.

FUTURE PERSPECTIVES

Clinical assessment requires more than merely deciding whether a particular disorder is present or not. Since treatment decisions and evaluation are usually not only based on diagnoses, the demand arises for a multimodal assessment of the individual patient in practice as well as research. In general, different sources of data, databases and functional ranges/constructs are to be taken into consideration in describing the patients (see Table 1). In research, the concept should be used more to validate instruments as well as to investigate disorders or compare different kinds of therapy. From a conceptual point of view the outcome should not be unidimensional operationalized, although statistical considerations always focus on a single outcome criterion (smaller sample size necessary). For clinical practice Ogles et al. (1996) proposed an organizational and conceptual scheme incorporating the dimensions of content, social level, source, technology and time orientation, which all have to be considered in choosing the most appropriate outcome measures. Content refers to the psychological areas and aspects which should be measured. The social level concerns the differentiation regarding the degree to which an instrument measures intrapsychic (internal) attributes of the patient or more broadly defined characteristics of the patient's interpersonal (external) world. The dimension source includes the decision as to which data source should be considered. Technology refers to the kind of assessment procedure (e.g. global versus specific assessment of a variable). The time-orientation dimension reflects the degree to which the instrument attempts to measure a stable (trait) or an unstable (state) variable.

CONCLUSIONS

A multimodal assessment contributes to a more complete understanding of the complex phenomena of short- and long-term courses of psychiatric disorders and their treatment as well as constructs in other areas of psychology (e.g. occupational psychology). This methodological concept is a valuable but often under-utilized strategy for the investigation of complex and multifaceted phenomena.

None of the various available methods clearly emerges as better than the others, as each has different strengths with respect to the aspects of validity. Not all points are equally accessible to all methods, because circumstances will prevent the proper implementation of one method or another. Major differences are evident among the methods in their potential to be structurally valid (Moskowitz, 1988). It is therefore to be recommended that multimodal assessment becomes standard in research as well as (clinical) practice.

MULTITRAIT–MULTIMETHOD MATRICES, VALIDITY: CONSTRUCT

MULTITRAIT–MULTIMETHOD MATRICES

INTRODUCTION

A multitrait–multimethod matrix (MTMM) refers to a matrix of correlations among multiple theoretical/empirical constructs (traits), each of which is defined operationally by a common set of measurement procedures (methods). Convergence and divergence principle provide a framework underlying the use of MTMM matrices in construct validation research: different operationalizations of a particular construct are expected to measure that construct (convergence) whereas constructs with different labels are expected to refer to different theoretical entities when measured by the same method (divergence). Developed over the past four decades, a large number of analytic methods are now available to analyse MTMM matrices.

Perhaps the most provocative challenge to logical positivism and its core concept of operational definitions of scientific concepts came from the pioneering work of Campbell and Fiske (1959). Definitional operationalism equates a scientific concept to the method (i.e. operation) of obtaining it. Consider, for instance, an IQ score of 110 obtained by using the Wechsler Adult Intelligence Scale (WAIS). The scientific concept of intelligence is defined operationally by the WAIS in this example. Hence, the score of 120 is 'the intelligence'. Despite the fact that there is no ambiguity as to what the intelligence is in this example, Campbell and Fiske argued convincingly that the score of 120 should be more appropriately labelled as 'the intelligence measured by WAIS'. The difference between these two labels is profound because there are other ways (i.e. methods) to measure intelligence, e.g. many other intelligence tests in the form of ratings and behavioural observations, neuropsychological measures, and educational attainments that do not necessarily provide congruent information about one's intelligence. After all, most widely used intelligence tests have less than half of their variances in common. Therefore, the influences of methods on test scores, which is considered as imperfect measures of theoretical constructs, need to be investigated empirically.

Trait measurement is an integral part of psychological assessment. To investigate the trait validity of psychological test scores and the potential biasing effect of measurement methods, Campbell and Fiske proposed the multitrait–multimethod matrix (MTMM), which is a matrix of correlations between multiple traits measured by multiple methods. Traits are conceptualized as individual difference variables which can only be observed indirectly, e.g. intelligence, depression, and self-esteem. There are often multiple procedures of measuring traits. Standardized operations defining the processes of trait measurements are usually referred to as methods, e.g. self-report, direct observations, and supervisory ratings. A measure refers to a trait–method unit, e.g. aggression measured by teacher rating. The MTMM matrix, formed by correlating multiple

Table 1. Multitrait–multimethod matrix

measures, contains information on traits, as well as methods.

MTMM MATRICES

For illustration purposes, an MTMM matrix of four traits, i.e. social problems (soc), attention problems (att), rule-breaking behaviour (rbb), and aggressive behaviour (agg), measured by three methods, i.e. ratings from mother (M), teacher (T), and self (S), appears in Table 1. The MTMM matrix was obtained by the administration of Child Behaviour Checklist, Teacher's Report Form, and Youth Self-Report instruments to 1934 school-age individuals (Achenbach & Rescorla, 2001). The measure labels indicate the method followed by the trait, e.g. T_rbb for teacher's report of rule-breaking behaviour and S_att for self-reported measure of attention problems. Campbell and Fiske classified the MTMM correlations into three sets: (a) different-trait/different method, (b) different-trait/same-method, and (c) same-trait/different-method.

Psychological assessments often utilize test scores which are subject to systematic and random errors of measurement. An inference from a directly observable measure to an unobservable trait requires justification. The MTMM matrix is a powerful tool to make such a justification by investigating convergent validity, discriminant validity, and method-effect. A successful demonstration of convergent validity assures that multiple methods provide congruence information about a particular trait. Large correlation coefficients between multiple measures of each trait (i.e. same-trait/different-method correlations) are consistent with convergent validity requirements. Conversely, trait measurement is suspect if each method provides only a unique aspect of a trait. All measurement methods ideally provide the same rank ordering of individuals for a particular trait.

Discriminant validity requires that correlations between different traits (or traits labelled differently) be less than perfect when measured with the same method. Consider, for example, self-report measures of rule breaking behaviour and aggressive behaviour. When almost all individuals rate themselves high on one measure, also rate high on the other yielding a correlation very close to unity, it casts doubts about rule breaking behaviour and aggressive behaviour as two different traits. A less-than-unity correlation, in a strict sense, may be viewed as a necessary but not sufficient condition to establish discriminant validity. The two traits should not only be different, but also the difference between the two should be meaningful. Once the necessary condition is established through the MTMM matrix (a less-than-unity correlation), further studies may reinforce the discrimination by revealing, for example, that neuropsychological mechanisms underlying two traits are different, traits have different sets of predictors, and they predict different outcomes.

Method effect alters trait correlations by means of introducing systematic biases on trait measures. In turn, distorted trait correlations have ramifications on trait scores, as well as the interpretations of convergent and discriminant validity evidence. Ideally, a measure contains no method effect. In contrast, MTMM studies have shown overwhelmingly that psychological and educational test scores contain a substantial amount of method effect. Examples of method effect include observers

(e.g. mother, father, and teacher reports), response tendencies in rating forms, social desirability, and response format. Pervasiveness of method effect in psychological measures is yet to convince methodologists to study method effect rigorously over the last four decades (Cronbach et al., 1972).

STATISTICAL ANALYSIS

Over a dozen techniques have been proposed to analyse the MTMM matrix with various degrees of complexity ranging from visually inspecting correlation patterns to modelling trait and method effects in a multiplicative fashion. The method proposed by Campbell and Fiske (1959) involved averaging correlations and eyeballing correlation patterns in the MTMM matrix to determine discriminant validity, convergent validity, and method effect. Their method was viewed as intuitive with no reference to any statistical theory. The random ANOVA model, originally proposed to analyse the MTMM matrix, by Kavanagh, MacKinney, and Wolins (1971), gained popularity early on. As demonstrated by Dumenci (2000), these two methods essentially share the same strengths and limitations. Despite their simplicity, both methods require that different-trait/different-method correlations be zeroed up to sampling variability, an assumption often violated in practice. The MTMM matrix in Table 1, for example, is no exception in this regard as the different-trait/different-method correlations reach up to 0.35. Also, differences in scaling factors are obstacles to the validity of inferences drawn from these methods.

Commonly employed methods for analysing MTMM matrices are listed in Table 2. Exploratory factor analysis (Jackson, 1969), non-parametric ANOVA (Hubert & Baker, 1978), partial correlations (Schriesheim, 1981), smallest space analysis (Levin, Montag & Comrey, 1983), equal-level approach (Schweizer, 1991), and constrained component analysis (Kiers, Takane & ten Berge, 1995) are among the exploratory methods for analysing the MTMM matrix. Popularity of exploratory techniques are overshadowed by widespread use of yet another exploratory method of Campbell and Fiske criteria, as well as emerging confirmatory models for the analysis of the MTMM matrix.

Confirmatory models for the MTMM matrix includes a variety of factor analytic models, covariance component analysis, and composite direct product models. Ability to perform hypothesis testing is a distinguishing characteristic of confirmatory models. Those confirmatory models that generate a substantively different MTMM matrix than the observed MTMM matrix preclude making any construct validity claims. When the model-implied MTMM matrix is consistent with the observed MTMM matrix, as judged by statistical criteria, inferences on discriminant validity, convergent validity, and method effect have a stronger footing than those inferences

3 Composite direct product models	Browne (1984)

originating from exploratory methods. It is perhaps this disconfirmability characteristic that has made the confirmatory models a preferred statistical approach in analysing the MTMM matrix.

Confirmatory factor analysis (CFA) has roots in true-score test theory (Lord & Novick, 1968) and was popularized by early contributions from Joreskog (1971). When applied to the MTMM matrix, the original CFA model of MTMM matrix involves t trait plus m method factors. Assumptions include orthogonal trait–method correlations and uncorrelated unique variables. Overparameterization of the MTMM matrix, convergence problems in obtaining an admissible solution, and out-of-range parameter estimates are commonly encountered problems in this classical CFA model for the MTMM matrix. Several remedies have been suggested to overcome these statistical problems leading to a new generation of CFA-MTMM models. Early modifications included the replacement of m method factors with correlated unique variables (Marsh, 1988) and respecification of each trait–method unit as a common factor by collecting data from multiple indicators for each trait–method unit (Marsh & Hocevar, 1988). These early modifications of the CFA-MTMM model have marginal benefits. The former modification has little value in understanding how the method effect operates on the measures whereas the latter attempted to find methodological solutions to statistical problems. Eid (2000) argued convincingly that the problem with the original CFA-MTMM model is that it has too many method factors. Thus, the resolution offered by Eid is to estimate m–1 method factors.

Covariance component analysis (CCA), a factorial random-ANOVA design, is founded in the generalizability theory of Cronbach, Gleser, Nanda, and Rajaratnam (1972). Applications of CCA principles specifically to MTMM matrices was developed by Wothke (1984, 1987). In addition to a general factor, which accounts for common elements in all measures, two sets of contrast factors, i.e. $t-1$ trait and $m-1$ method, are estimated from a CCA. Trait contrast factors reveal differences between all possible sets of traits, whereas method contrast factors elicit variability between all possible sets of methods. Scale unreliability and scaling differences between measures are taken into account in CCA. Unidirectional relations between scaling and contrast factors are fixed a priori. The matrix containing these fixed coefficients are called columnwise orthonormal in which the sum of squares is equal to unity for each column and the sum of cross-product terms is zero for all column pairs. CCA has several attractive features. CCA follows the multivariate statistical theory underlying MTMM matrices. Evaluations of method effect, convergent validity, and discriminant validity are made after taking into consideration a general factor, differences in scaling of measures, and measure unreliability, all of which are characteristics of commonly encountered psychological measures.

A common characteristic of MTMM models discussed so far is that the functional relations between trait and method factors are formulated in an additive fashion. Under additivity, it is expected that the magnitude of differences between different-trait/same-method correlations and different-trait/different-method correlations is zero up to the sampling variability for all trait pairs. The finding that the method effect varies as a function of the magnitude of different-trait/same-method correlations led to the development of the composite direct product (CDP; Browne, 1984) model in which multiplicative trait–method relations is explicitly modelled. Trait and method multiplicative correlation components, estimated from the CDP model, are then used to evaluate trait validity (i.e. convergent and discriminant) and method effect. Despite its statistical sophistication of handling multiplicative trait–method relations, applications of the CDP models are limited in psychological literature perhaps due to the unfamiliarity and apparent complexity of such models to a typical researcher in psychology. Even in its simplest form, i.e. the structural equation modelling specification of CDP models, a relatively high level of expertise is needed to implement CDP models.

CONCLUSIONS

Complete psychological assessment of individuals inevitably requires measures relatively free from systematic and random errors of measurement. The MTMM matrix is perhaps the most simplistic, yet effective, tool to evaluate trait validity of test scores utilized widely in psychological assessment. Despite the advances in trait measurement over the second half of the 20th century, the method effect remains a thorny issue by posing a serious challenge to the validity of

inferences drawn from test scores in psychological assessment. Trait validity is an ongoing process of improving our confidence in making inferences from test scores. The MTMM analysis is an effective tool in this process.

Design issues need to be taken into consideration in analysing MTMM matrices. A cross-sectional design is a rule in a typical MTMM study. Longitudinal designs also are vulnerable to the method effect even more than cross-sectional studies due to the repeated administrations of a set of measures. Most statistical models of change either totally ignore the issue of method effect or leave it unexplained by common factors (e.g. Kenny, 1995). There certainly are some exceptions. The $t-1$ method factor specification appears to be a sound strategy not only in cross-sectional designs (Eid, 2000) but also in longitudinal models of change as well.

Advances in the analysis of MTMM matrices parallel closely to the advances in structural equation modelling (SEM) over the last four decades. Recent developments in the SEM, particularly in the areas of nominal/ordinal data, missing data methodology, and non-linear/non-normal data, have considerable potential to expand the current scope of construct validity research. The SEM approaches are especially useful for exploring the method effect at item level while traits are evaluated within the latent variable framework.

THEORETICAL PERSPECTIVE: PSYCHOMETRICS, MULTIMODAL ASSESSMENT, VALIDITY: CONSTRUCT

NEEDS ASSESSMENT

INTRODUCTION

Needs assessment can be broadly defined as a systematic set of procedures to identify needs, prioritize them and make decisions concerning programme improvement based on these needs (Witkin & Altschuld, 2000). There are many different approaches to need definitions; for example, Bradshaw (1972) proposed a taxonomy of four types of social needs – normative, felt, expressed, or comparative needs – whereas McKillip (1987) suggested that need was a 'value judgement that some group has a problem that can be solved' (p. 10). A need is generally considered to be a discrepancy between a desired state of affairs and the present state of affairs in regard to a group and a situation of interest (Kaufman, 1988). Needs assessment seeks to determine and analyse such discrepancies and to set priorities for future action.

Sometimes it is difficult to see the distinction between needs assessment and other forms of programme planning. In general, needs assessment is done prior to programme planning and focuses on the ends to be achieved, rather than the means, although needs assessment data can form the basis for selecting the means (Anguera & Chacón, in press).

In this context, the first major problem is to conceptualize needs in order to be able to operationalize them. Social problems have to be translated into needs, which have both quantitative and qualitative domains. Determining the qualitative domain of a social problem involves labelling the situation in relation to theoretical constructs. To determine the quantitative domain, one must identify similarities between persons and groups that experience the same problems in order to categorize them and plan possible interventions to solve those problems (Kettner, Moroney & Martin, 1990). If standards of need are assumed to be relative, there must be a base group to serve as a standard against which to evaluate levels of needs. In needs assessment, the comparison group is most appropriately the community of which the target population is a part. So, we have to identify and study our real affected population, and not necessarily accept population statements about 'wants' as 'needs', as their wants can be different from our designed standards of need.

NEEDS ASSESSMENT PHASES

Needs assessment can be considered as applied social research. It entails a systematic process of conceptualizing a research design, and gathering and analysing data according to accepted standards of social science, and its results are used to inform policy and programme development. Following this logic, Witkin and Altschuld (2000) present a comprehensive process of needs assessment which considers three

sequential phases, each concluding with a written product:

> *Phase 1: Exploration*: The functions of the exploratory phase are to determine what is already known about needs; to identify major areas of concern; and to decide on system boundaries and potential sources of data. In addition, phase 2 is designed during phase 1, and criteria for evaluating the needs assessment as a whole are developed.
> *Phase 2: Data gathering*: Information is gathered and analysed based on (a) archival data; (b) communication processes; and (c) analytical processes.
> *Phase 3: Utilization*: Phase 3 is the bridge between (1) findings from the data and (2) plans for action. It implies setting priorities and criteria for solutions, weighing alternative solutions, and formulating action plans, while considering the allocation of resources.

METHODS FOR CONDUCTING NEEDS ASSESSMENT

Having considered needs assessment as applied social research, we can see that the range of methods used in needs assessment is potentially the same as that available to all applied social researchers. There is no standard method for conducting needs assessment; in fact, we strongly endorse using two or more methods of gathering data on which to base the assessment. At this point it is important to state that data-gathering methods by themselves are not a needs assessment. Needs assessment is a total decision-making process, in which data are but one component. Needs assessment is not a 'top-down' activity, in which a few people decide the needs to be addressed. On the contrary, it implies a democratic involvement of different stakeholders. Furthermore, the active involvement of different groups of stakeholders not only ensures that information takes into account different perspectives but also increases the likelihood that the results of the needs assessment will be used in appropriate programmes.

In order to verify the most frequent tools for gathering data for a needs assessment, we did a review of the literature using WebSPIRS software. We obtained 2075 articles where the term 'needs assessment' appeared in the title and/or in the abstract. We consulted the following databases from 1997 to the present: Current Contents, Sociological Abstracts, Humanities Index, ERIC and PsycINFO. In each type of data gathering method, we give the percentage of articles reviewed that used these methods.

Questionnaires

Surveys, especially in the form of written questionnaires, are the most frequently used tools for gathering data in needs assessment, either alone or in conjunction with other methods (42%). The main advantage of questionnaires is that they are relatively easy to administer. They can be administered to either large or small groups, and respondents can be anonymous and do not have to be physically present. In addition, the use of questionnaires may be less expensive than other types of data gathering. Standardized, structured questionnaires provide quantitative information. But the non-structured/semi-structured non-standardized ones can also provide qualitative information.

Interviews

We found that interviews are the most frequent alternative or complement to the written survey (21%). Their principal characteristic is that the interviewer asks the questions and records the answer. Structured or semi-structured interviews are the most frequent. Their main advantages are that they can give immediate feedback and that they are flexible tools (their structure, contents, protocol, and so forth can be changed through the interview process). Interviews mainly provide qualitative information.

Group Processes

After surveys, group processes are the most widely used method for gathering opinions and data for needs assessment (10.5%). Group processes are important because they constitute an optimal procedure for taking the views of different stakeholders into consideration. The community group forum, the nominal group technique, and the focus group interview have become the most frequent basic group processes in needs assessment.

Generally, group processes proceed through three major stages: (a) Planning (establishing purposes for the meeting; deciding on sampling, meeting site, structure, procedures, and leadership; inviting participants); (b) Implementation (different for each type of process that we will point out); and (c) Follow-up (use results, communicate results in a timely fashion to key decision makers and stakeholders).

Following these global phases, the first type of group process, the community forum, is mainly used to gather stakeholder concerns of need areas, opinions regarding quality, and exploration of community values. The forum is most effective with a group of about 50 participants. Usually the size is quite large. The second type, the nominal group technique, is most frequently used as a small group technique; the group is generally made up of 6 to 10 participants. The main objective of the nominal group technique is to produce a large number of ranked-ordered ideas in a relatively short period of time. One of the main characteristics of this technique is that the group members do not interact as they would in other group processes. Finally, the focus group interview is a structured process for interviewing a small group of, usually, between 8 and 12 individuals. Its purpose is to obtain in-depth views regarding the topics of concern. Obtaining a consensus is not the goal. This technique provides an opportunity for participants to hear the views of the other members as well. Interactions in the focus group interview flow in two ways: between group members and between participants and the leader or coordinator of the group.

Archival Research

When archival data are available and fits the focus of the needs assessment, they are valuable and should be used (6.5%). The use of existing records is generally cheaper and requires less time than creating new data sets. Such resources often have problems of quality and accuracy. They should be used only after seriously analysing their quality.

Literature Review

This method presents similar advantages and disadvantages to archival data and is used in the same proportion (6.5%). The major problem with this procedure is that such reviewed records are rarely designed expressly for the purpose of needs assessment and, consequently, they can present additional problems of interpretation and validity.

Other Kinds of Specialized Surveys and Group Techniques

In addition to the preceding group of methods, we found a less frequent mixture of different types of data-gathering procedures in our literature review (indicators, critical incidents, preference inventories, advisory councils, and so forth). Depending on the context in which NA is carried out, we can combine the previously described, more usual techniques with different and novel approaches. The key point is to clearly determine the purpose of the specific needs assessment in order to select the proper data-gathering method or combination of methods.

DATA ANALYSIS AND INTERVENTION CONTEXT IN NEEDS ASSESSMENT

Data analysis in needs assessment is theoretically oriented to causal analysis, examining needs in terms of their potential causes, particularly with regard to identifying those factors that can be changed with the available resources. Nonetheless, in our literature review we found that in actual practice during the last five years more than 60 per cent of reviewed records only used descriptive statistics, 8 per cent presented multivariate analysis, and the rest of the papers presented basic and classical inferential analysis (regression, Chi-squared, ANOVA, McNemar test, and so forth).

Given that it can be implemented in any organization or agency service, needs assessment presents a wide diversity of intervention areas. Our study of several hundred needs assessments that were conducted from 1997 showed that needs assessment is more frequent in social and health areas than in education. Specifically, some of the major areas in health programme applications are related to programmes for the elderly, physician and nurse training programmes, HIV/AIDS studies, neuropsychology, cancer, mental illness, sexuality, coronary heart diseases, and healthy eating (i.e.

Buhler, Oades, Leicester, Bensley & Fox, 2001). On the other hand, in the social intervention context we found the following main intervention areas: interventions with family or persons with illnesses, patients at risk, the unemployed, children with divorced parents, sexuality, and students with disabilities (i.e. Borgen, 1999). In the educational area we found some applications on school violence, training programmes for teachers, adult students, and continuing education (i.e. Coggeshall & Kingery, 2001).

FUTURE PERSPECTIVES

In the future, needs assessment will continue to be important, and may even grow in importance; however, those scholars and practitioners conducting needs assessment must pay attention to two important points.

First, new technologies will facilitate a rapid gathering and analysis of information from disparate groups of stakeholders. This is related to groups communicating electronically, new strategies for concept mapping, and analysis of Delphi responses (Scrimshaw & Hurtado, 1987). There has been very little empirical research on needs assessment. Because of this, more comparative studies of different methods of data gathering, as well as syntheses of different research efforts, will be needed in order to enhance other, more sophisticated techniques different from descriptive analysis.

Second, those interested in needs assessment must weigh the needs of individuals and partial groups with national or regional interests (Leviton, Finnegan, Zapka, Meischke, Estabrook, Gilliland, Linares, Weitzman, Raczynski & Stone, 1999). How can this be achieved? Macro-level needs assessment (usually using national statistics and indicators) must be combined with micro-level needs assessment (based on group processes and rigorous qualitative methods).

CONCLUSIONS

Needs assessment consists of determining, analysing, and prioritizing needs and, in turn, making decisions concerning strategies to resolve high-priority needs. After reviewing 2075 papers related to needs assessment published between 1997 to October 2001, it is clear that it is important to increase the use of more specific instruments for data gathering in addition to surveys and to use more precise analytical techniques in addition to descriptive statistics.

When carrying out a needs assessment process, we have to take into account four main factors that are basic to be successful: (a) proper consultation of the real affected population; (b) differentiating between population statements about 'wants' and 'needs'; (c) using needs assessment as a participatory process, not a 'top-down' process; and (d) understanding that different methods should be used for gathering information, but that the methods themselves are not a needs assessment.

Evaluation: Programme Evaluation (General), Evaluability Assessment

NEUROPSYCHOLOGICAL TEST BATTERIES

INTRODUCTION

Given the progress in neuroimaging methodology, it is not the primary task of neuropsychological test batteries to detect brain injury. Today, neuropsychological testing has to meet more specific tasks, especially the evaluation of rehabilitation programmes and neuropsychological trainings. The first part of this contribution refers to impairment, disability, and handicap as three different levels of neuropsychological assessment. Following an explication of tasks and problems of neuropsychological assessment in the second part, relevant aspects of neuropsychological functioning are differentiated and diagnostic tools for the assessment of attention, memory, dementia, coping with illness, emotional status, and specific executive functions are presented.

LEVELS OF NEUROPSYCHOLOGICAL ASSESSMENT

Proceeding from the terminology proposed by the WHO (see Matthesius et al., 1995), possible long-term consequences of brain damage and effects of neuropsychological rehabilitation can be conceptualized according to the three levels of impairment (i.e. amount of the damage itself, e.g. damages in basic processes of memory, concentration, and perception), disability (i.e. resulting functional losses, e.g. decreases in working performance attributable to memory, concentration, or perceptual disorder), and handicap (i.e. disadvantage in social functioning, e.g. job discrimination). Corresponding to this differentiation, three aims in the treatment of neuropsychological problems can be distinguished: restitution (i.e. full recovery of functional status), compensation (i.e. enabling the person to compensate successfully for every-day consequences of impairment), and adaptation (i.e. adjusting environmental conditions so that the person is able to lead an independent life).

According to Wilson (1997), simply focusing on drill and exercise, most cognitive training programmes in neuropsychological rehabilitation proceed from the impairment level. This kind of training programme has been said to be useless for brain-damaged persons, since a restitution of cognitive abilities is often impossible. Instead, Wilson (1997) proposed neuropsychological rehabilitation to focus on the disability-level. Proceeding from neuropsychological knowledge, educational programmes should enable patients to compensate for individual problems attributable to neuropsychological impairment. Consequently, behavioural therapy is seen as a basis for developing individual training programmes, aimed to optimize patients' performance in everyday activities. From a practical perspective, training programmes should not be restricted to the improvement of basic processes (i.e. hoping for a generalization of regained skills and abilities) but should also consider the importance of environmental conditions for the relationship between competencies and actual performance. Focusing on the respective relevance in patients' everyday life, it can be argued that exactly those activities, that are usually expected to benefit by means of generalization, should be trained in rehabilitation programmes.

Nevertheless, all the three levels differentiated in the WHO-classification are of high relevance for neuropsychological assessment. First, none of these levels can be ignored since the development of individual intervention measures as well as the evaluation of effectiveness and usefulness of rehabilitation programmes must rely on information about the kind and severity of impairment, disability, and handicap. To give an example, proceeding from the impairment-level it might be obvious that a training aimed to improve memory performance should be offered. However, it is not enough to claim that patients' memory performance in a specific psychometric test could be improved due to the participation in a cognitive training. Additionally, to establish the effectiveness and usefulness of the respective intervention measure, it must be shown that patients do suffer from less memory problems or are more effective in managing memory tasks after their participation in the respective programme than before.

Corresponding to the differentiation between impairment, disability, and handicap, three methodological approaches of neuropsychological assessment can be distinguished: (1) Diagnostics of impairment using psychometric instruments. Here, diagnosis of impairment is often identical with establishing the presence or absence of neuropsychological symptoms or syndromes. Examples are measuring intelligence or memory capacity with standardized tests or assessing neglect by means of perimetry. (2) Diagnostics of functional capacity establishing degrees of (in-)dependency in managing every-day tasks. Examples are lists of activities of daily living, including questionnaires developed especially for patients suffering from specific neuropsychological disorders, e.g. for assessing communicative effectiveness or cognitive failures. (3) Diagnostics of social consequences using scales to determine degrees of social integration (e.g. in contexts of job and family) and other psychosocial factors.

TASKS AND PROBLEMS OF NEUROPSYCHOLOGICAL ASSESSMENT

Just as psychological diagnostics in general, neuropsychological diagnostics was characterized from the beginning as status diagnostic: aimed to register the actual status of a person in different areas of psychological functioning, whenever possible in relation to a relevant comparison group. Results of neuropsychological diagnostics have long been used as decisive criteria for the assumption of brain damage. The extensive neuropsychological test batteries, developed to estimate the probability of brain damage, are only seldom applied in a complete version today, since the question whether the assumption of brain damage seems justified or not has become obsolete, given the development of neuroimaging methods (e.g. Deutsch & Mountz, 2000). Global measures of psychological functioning, e.g. intelligence scales, are still in use today, either as an indicator of personal competencies or as a means of validating new developed methods of neuropsychological screening. Today, compared with traditional methodological approaches, neuropsychological assessment must answer more specific questions; neuropsychological test batteries have to be evaluated against more specific criteria: first, rather than establish a global measure of decline in performance, neuropsychological test batteries should be able (a) to determine which specific aspects of performance are deficient, (b) to quantify the degree of deficiencies in the respective aspects of performance, and (c) to identify specific aspects of performance that might be improved by training or other intervention measures (Capitani, 1997). Second, neuropsychological test batteries should be suitable for documenting effects of neuropsychological training. The measurement of skills and abilities must be sensitive to the registration of even small changes in dependent variables, simultaneously being insensitive to artificial effects of repeated measurement (see Baddeley et al., 1980). Consequently, it has been argued that neuropsychological assessment should focus on basic processes (e.g. reaction times) underlying the observed complexity in psychological functioning (e.g. in the areas of perception, memory, intelligence, problem-solving, etc.). On the other hand, as already mentioned in the context of levels of neuropsychological assessment, the usefulness of rehabilitation efforts depends on significant effects on everyday performance; a detailed analysis of the impairment level must be complemented by an appropriate analysis of the disability level (Wilson, 1997).

The usefulness of neuropsychological screening tests like the Mini Mental State Examination, the Quick Cognitive Screening Test, or the Neurobehavioural Cognitive Status Examination in the evaluation of rehabilitation processes and outcomes depends on the initial level of cognitive capacity. Such screening tests only allow for an appropriate assessment of rehabilitation effects in the case of extreme deficits in patients' initial performance. Because of the limited value of screening tests for answering the questions sketched above as central topics of neuropsychological assessment, research on the effectiveness of rehabilitation programmes or more specific neuropsychological trainings generally depends on the use of neuropsychological test batteries allowing for a detailed assessment of deficiencies and competencies in the areas of attention, memory, coping with illness, visuo-perceptual information processing, executive functions, and neglect. Since the relevant information is often acquired by means of computer assisted diagnostics, i.e. tasks to be worked out by the subjects are presented on the PC-screen, solutions are encoded via keyboard and analysed by the respective software, it is reasonable to use the diagnostic tasks simultaneously as a basis for training programmes. However, it should be noted that training effects are of questionable validity if diagnostics simply repeat the content of the training (e.g. Knab, 2000).

Common problems of psychological diagnostics are of particular relevance in neuropsychological assessment. Many brain-damaged patients suffer from deficiencies in vigilance and emotional well-being, i.e. circumstances accounting for worse test performance in otherwise healthy subjects. Moreover, claims for indemnification, e.g. following an accident, might lead to an aggravation of symptoms of neuropsychological impairment (see Binder & Rohling, 1996; Nies & Sweet, 1994). As a consequence, a detailed analysis of potential biases in the test situation is a prerequisite for adequate neuropsychological assessment.

COMPONENTS OF NEUROPSYCHOLOGICAL TEST BATTERIES

Adequate assessment of neuropsychological status proceeds from detailed information about patients' personality, behaviour, mental abilities, learned skills, and rehabilitation potential. The necessary information is gained through a combination of different methodological strategies relying on different sources of information. As a rule, an exploration of premorbid history, including psychosocial information (see Sloan & Ponsford, 1995) and medical history (see Silver et al., 1997), can further the understanding of patients' problems and needs. However, observation is the foundation of all psychological assessment (Lezak, 2000). Neuropsychological assessment often relies on direct and indirect observations. Indirect observations include reports from caregivers, employers, family members, etc., who interact with patients in contexts, where the patient has no self-consciousness about being observed. Direct observations can be differentiated in informal observations, e.g. during an anamnestic interview, and psychological tests, i.e. 'a set of observations, made under standardised conditions for the purpose of measuring a characteristic or a set of characteristics with dimensional or multivariate features' (Lezak, 2000: 69). Psychological tests can be used in the assessment process to gain insight into behavioural phenomena, conditions, capacities, or states. Although typically conducted in artificial situations, psychological tests build an inevitable part of the assessment process, since formal testing – and only formal testing – allows for a comparison of patients' characteristics with relevant standards and norms and a documentation of behavioural changes in terms of their statistical significance.

Neuropsychological test batteries consist of a number of subtests which provide information about competencies and deficiencies in diverse areas of neuropsychological functioning. Since information about reliability and validity is available for each subtest of a given battery, subtests should be regarded as diagnostic tools that can be combined according to the information required for assessing the neuropsychological status of the individual patient. Consequently, in the following we do not focus on the portrayal of specific neuropsychological test batteries, e.g. the TAP (Zimmermann & Fimm, 1993), the ART-90 (Bukasa & Wenninger, 1986), or the Vienna Test System, as a whole. Instead, proceeding from the neuropsychological functions to be assessed, we will give a brief sketch of psychological tests that proved to be of sufficient reliability and

Table 1. Aspects of neuropsychological functioning and respective diagnostic tools

Aspects of neuropsychological functioning	Diagnostic tools
Attention	
(a) Alertness	Subtests of TAP, ART-90, and Vienna Test System
(b) Selectivity	Go/Nogo (TAP), Vienna Determination Test, d2, Stroop-Test
(c) Information processing capacity	Shared Attention (TAP), PVT (ART-90), Vienna Determination Test, Trail-Making-Test, ZVT (NAI), d2, PASAT
Memory	
(a) Short term memory	Subtests of WAIS-R, BAT, and ZVT (NAI)
(b) Working memory	Working Memory (TAP), PASAT
(c) Long term memory	Subtests of BAT and NAI, RBMT, LGT-3
(d) Orientation	Orientation Test for Rehabilitation Inpatients
(e) Dementia	MMSE, FAST, BCRS, NOSGER, ADAS, HIS, SIDAM, BAI
Coping with illness and Emotional status	
(a) Coping with illness	TSK, FKV
(b) Coping with pain sensations	SVS
(c) Emotional disorders	DSM-III-R/DSM-IV, ICD-10
(d) Depression	CDS
Executive functions	
(a) Mental flexibility	WCST, Trail-Making-Test, BCT, Means-Ends–Problem-Solving-Tasks
(b) Concept development	Subtests of LPS and IST-70

validity and therefore can be combined in individual neuropsychological test batteries. Since the assessment of visuo-perceptual impairment and neglect is described in detail in another contribution to this encyclopaedia, this entry concentrates on diagnostic tools for the assessment of four aspects of neuropsychological functioning: (1) attention, (2) memory, (3) coping with illness and emotional status, and (4) executive functions (see Table 1).

Attention

This aspect of neuropsychological functioning has long been regarded as a single, homogeneous concept (e.g. in the sense of concentration). Today, following the work of Posner and associates (e.g. Posner & McLeod, 1982), attention is differentiated in the three components alertness, selectivity, and information processing capacity. Godefroy et al. (1996) could show that these components can be affected differently in brain damaged people.

(a) Alertness can be operationalized as simple reaction times or as sustained attention. Examples for the former are the subtest Alertness of the TAP, testing reaction times after presentation of visual stimuli, and a subtest of the Vienna Test System, testing reaction times after presentation of auditory stimuli. Examples for the latter (sustained attention) are the TAP-subtest Visual Vigilance and the VIGO-subtest of the ART-90.

(b) Tests of selectivity require the consideration of diverse stimuli and a selection among alternative responses. Well established are the Go/Nogo-subtest of the TAP, the Vienna Determination Test from the Vienna Test System, specific concentration tests like the d2 or the Stroop-Test.

(c) Information processing capacity is operationalized via tests of shared attention and tests of speed of information processing. Examples for the former are the subtest Shared Attention of the TAP, the subtest PVT of the ART-90, and the Vienna Determination Test of the Vienna Test System. Examples for the latter are the Trail-Making-Test, part A, the ZVT of the Nuremberg Age Inventory (NAI), the d2, and the Paced Auditory Serial Addition Test (PASAT).

Memory

Regarding this aspect of neuropsychological functioning, it should be at least differentiated between short term memory, working memory, long term memory, and orientation (concerning time, place, situation, and person). Moreover, in the context of severe deficits in memory and orientation the diagnosis of dementia is an important task for neuropsychologists.

(a) Short term memory is often operationalized via repeating lists of words or numbers, well established are the subtests of the WAIS-R (Wechsler Adult Intelligence Scale – Revised), the BAT (Berlin Amnesia Test), or the ZVT subtest of the NAI. For the assessment of visual short term memory, good tools are the Benton-Test and the subtest Pattern Recognition of the BAT.

(b) Working memory can be assessed via the subtest Working Memory of the TAP, requiring processing of visual stimuli, or via the PASAT, requiring processing of auditory stimuli.

(c) Long term memory can be assessed, e.g., via five subtests of the BAT (Unstructured Recall, Semantic Interference, Recognition, Proactive Interference, Recall with Semantic Structure), via the subtest Word List of the NAI, or via more extensive tests of learning and memory which also allow for comparison of performance with verbal versus non-verbal materials or an analysis of topographic memory (see e.g. Rivermead–Behavioural-Memory-Test, RBMT; Learning and Memory Test, LGT-3).

(d) A good tool for testing orientation in inpatient rehabilitation has been developed by Cramon and Säring (1982). Unfortunately, this scale can not be used for neuropsychological assessment in the context of ambulant rehabilitation.

(e) The Mini Mental Status Test is well established in the assessment of severe cognitive deficits. A similar diagnostic tool has been proposed with the Zürcher Variante. Another diagnostic tool for the assessment of dementia, the Functional Assessment Staging (FAST), has been developed from the Brief Cognitive Rating Scale (BCRS). The FAST primarily focuses on questions of everyday competence and independent care, whereas the BCRS focuses primarily on the degree of cognitive impairment. The Nurses' Observation Scale for Geriatric Patients (NOSGER) is a good complement to other scales for the assessment of dementia, since it relies on observations of caregivers. Similarly, the Alzheimer Disease Assessment Scale (ADAS) consists of two parts: an interview and an observation of a patient's behaviour. The Hachinski Ischemic Scale (HIS) can be used for a differentiation between Alzheimer and multiinfarct dementia. Moreover, two structured interviews were proposed for the assessment of dementia: the SIDAM, a structured interview for the diagnosis of Alzheimer dementia, multiinfarct dementia, and other kinds of dementia, and the Brief Assessment Interview (BAI).

Coping with Illness and Emotional Status

Assessment of this aspect of neuropsychological functioning can rely on several psychometric scales, e.g. TSK or FKV, that allow for a reliable and valid measurement of coping strategies, which can be interpreted as dimensions explaining for the variance observed in patients' reaction to symptoms and deficiencies. Moreover, it can be useful to explore patients' coping with pain sensations. Here, the SVS (Klinger & Morawetz, 1993) can be regarded as a good diagnostic tool.

As a consequence of insufficient adaptation to neuropsychological problems, patients can develop severe emotional disorders. Therefore, it must be analysed whether patients meet the diagnostic criteria explicated in the classification of ICD-10 or DSM-III-R/DSM-IV. Moreover, neuropsychological assessment should integrate psychometric scales to gain insight into patients' emotional status. Several psychometric scales allow for a reliable and valid measurement of depression, control beliefs or anxiety. However, especially at the beginning of neuropsychological assessment and rehabilitation, patients' deficiencies might force the clinician to do without the initial application of self-rating scales and to rely on

extrospective information instead. However, the Cornell Depression Scale, originally developed for the assessment of depression in patients suffering from dementia (Alexopoulos et al., 1988), is a diagnostic tool primarily relying on the observation of patients' behaviour and requiring only a minimum of cognitive abilities.

Executive Functions

Only a part of the neuropsychological assessment of executive functions relies on standardized psychological tests. Since deficiencies in executive functions primarily become apparent in ecologically valid analysis of everyday activities, cognitive and emotional status tests are only of minor relevance in the assessment of this aspect of neuropsychological functioning (e.g. McCarthy & Warrington, 1990). Nevertheless, some executive functions, especially mental flexibility and concept development, can be assessed through psychological testing.

(a) Mental flexibility can be operationalized via tendencies of perseveration or via change of routines. Good diagnostic tools are the Wisconsin-Card-Sorting-Test (WCST), the Trail-Making-Test, part B, the Booklet Category Test (BCT), and the Means-Ends–Problem Solving Tasks (Spivack et al., 1976).

(b) Concept development can be assessed via measures of word fluency and reasoning. The respective subtests of the LPS and the I-S-T-70 are diagnostic tools of high reliability and sufficient validity.

FUTURE PERSPECTIVES AND CONCLUSIONS

It has been shown that reliable and valid diagnostic tools are available for assessing aspects of neuropsychological functioning. However, components of neuropsychological test batteries too often focus exclusively on basic abilities and skills, i.e. the impairment level of neuropsychological assessment. Unfortunately increasing performance in tasks requiring basic abilities and skills cannot be regarded as an indicator of effective rehabilitation as long as the generalization of these advances has not been proven. As a consequence, further research is needed to improve our understanding of the relationship between impairment and disability. Putting forward the assessment of the disability level is a prerequisite for such research.

NORM-REFERENCED TESTING: METHODS AND PROCEDURES

INTRODUCTION

This entry provides a definition of norm-referenced testing emphasizing its specific characteristics as it pertains to educational and psychological testing. The different uses and applications of norm-referenced tests as highlighted by the most popular types of comparisons made are also noted. Third, the advantages and disadvantages of norm-referenced testing are discussed while future applications and uses of norm-referenced testing are described in the concluding section.

DEFINITION AND CHARACTERISTICS OF NORM-REFERENCED TESTING

Norm-referenced testing refers to the process of developing and applying tests to enable the interpretation of an examinee's score relative to that of other examinees. Norm-referenced tests provide answers to the question: 'How much of the measured construct does a person possess in relation to the comparable norm group?' Norm-referenced testing differs from criterion-referenced testing (CRT) as the primary purpose is to determine how examinees compare to each other and not to what examinees know or can do. While the use of information from these tests might differ, for both norm- and criterion-referenced tests, many of the same stringent test development procedures have to be followed.

The distinguishing characteristics of norm-referenced tests noted by Popham (1990), Thorndike (1997), and many others include:

- individuals are placed on a continuum defined by a range of particular behaviours expressed in a specific population;
- a quantitative answer to the question 'Where does this individual rank relative to that of a specific-referenced group?' is provided;
- items typically span the entire range of difficulty values;
- standards of performance are not inherent in the instrument and are only defined after the distributions of scores have been determined;
- no set minimum passing score is defined a priori;

- test scores are expected to show considerable variability.

USES AND APPLICATIONS

The primary reason for using norm-referenced testing is to discriminate among examinees; that is, to highlight differences among examinees by producing a dependable rank order of examinees on the construct measured by the test. Typically, most aptitude, interest, and personality inventories are norm-referenced since there are no universally acceptable or relevant criteria to compare the scores against. Norm-referenced testing provides useful information for making decisions in the worlds of learning, work, and play; for example, determining appropriate development levels of children with specific difficulties or selecting the most suitable applicant for a job.

In practice, comparisons in performance among examinees are made using norm tables. Norm tables provide a frame of reference for interpreting the scores of particular examinees in comparison to the particular normative group that defines the set of standards (Murphy & Davidshofer, 1998). Depending on the purpose of testing, norm tables can be developed at different levels (national, local) and for different samples of the population (e.g. males and females or second language speakers). It is important to note that norm tables can only be developed for instruments in which a total score can be calculated, for example a test or a scaled questionnaire. However, if norm tables are to be useful, they must be based on recent data, be representative of the population, and be relevant to the group of interest (Murphy & Davidshofer, 1998).

The process of constructing norm tables, called norming, can be a complex, costly, and time-consuming process that usually entails two stages: (1) the test is administered to a representative sample of examinees for whom the test was developed; and (2) the raw scores obtained on the test are converted to scale scores that define the type of norms developed. Three additional points need to be noted. First, norms can only be developed for standardized tests. If tests are not standardized, by definition any comparison would not make sense as examinees take the test under different conditions. Second, norm tables must be completed before any norm-referenced test scores are released. Third, all norm tables have to be regularly updated since norm groups (especially national samples) generally change over time. Depending on the purpose and use of the test, norms are typically updated every 5 to 8 years.

A thorough discussion of the different types of norm tables, the different ways of classification, the procedures for calculating these tables, and the specific advantages and disadvantages of each type is beyond the scope of this entry. Instead, the most common norm tables used, namely percentile ranks, normalized standard scores, developmental scales, and deviation IQ scores (Murphy & Davidshofer, 1998; Nitko, 1996), will be briefly discussed.

Percentile Ranks

Percentile ranks indicate the percentage of examinees from the norm group that falls below a specific raw score. For a particular examinee, the percentile rank indicates the percentage of persons that s/he has outscored in the norm group of interest. For example, a person with a percentile rank of 79 has outscored 79% of the examinees on whom the test was normed.

Normalized Standard Scores

Normalized standard scores are raw scores from a norm group that have been transformed via a non-linear transformation to approximate a normal distribution. Two types of scores frequently used include the normalized z-score (mean 0 and standard deviation 1), and the normalized T-score (mean of 50 and standard deviation 10). For example, the performance of a person with a normalized z-score of 2 (T-score of 70) is similar to the performance of the top 3% of the norm group.

Developmental Scales

Developmental scales compare an individual to that of the average person in the norm group at a similar age or grade level. Paediatricians, for example, commonly use age equivalent scales to ascertain whether children are undergoing any unusual growth patterns by comparing the height or weight of a child to the expected rate of

growth for children of a similar age. Grade equivalent scales, expressed as a decimal 4.5 to indicate the 4th grade and 5th month, provide information on how an examinee's score compares to other examinees at various grade levels. For example, a raw score of 43 which may have a grade-equivalent score of 7.0 indicates that the examinee performs at the level of a student beginning the seventh grade.

Deviation IQ Scores

The IQ score, probably one of the most debated and controversial topics in the field of psychological assessment, was originally proposed as an index of intellectual development and defined as the ratio of the examinee's mental age to his/her chronological age. To address the shortcomings of the IQ score, defined as a ratio of mental age to chronological age, the deviation IQ score, with a mean of 100 and a standard deviation of 15, was introduced (Anastasi & Urbina, 1997). Deviation IQ scores range between 55 and 145 with scores at the higher end indicating above average performance and scores at the lower end indicating below average performance.

ADVANTAGES AND DISADVANTAGES

The advantages and disadvantages of any testing process must be considered in the context for which the testing is conducted. One advantage of norm-referenced tests is that these tests provide a basis for comparing examinees when making selection and/or diagnostic decisions. This is especially relevant in the context of psychological assessment where there are no fixed criteria or performance standards to compare against. In addition, norm-referenced tests are often broader in focus than criterion-referenced tests and are more useful in providing a broad overview of examinee performance (Popham, 1990).

The biggest disadvantage usually associated with norm-referenced tests is that little information is provided regarding what an examinee knows or can do. This disadvantage, however, is mainly applicable to achievement testing. A second disadvantage relates to the interpretation of norms as standards. In this context, the emphasis should be on how people *currently* perform and not on how they *should* perform. This issue, however, can easily be addressed by ensuring that norm tables are properly used.

FUTURE PERSPECTIVES AND CONCLUSIONS

Three reasons for why norm-referenced testing is here to stay are as follows: (a) there is the natural tendency for humans to want to know how others are doing and where we fit in; (b) there is the need for greater information to facilitate improved decision making, which is especially relevant for accurate diagnosis and identification of appropriate intervention strategies; and (c) in the context of a general lack of fixed or agreed-upon criteria, norm-referenced information at least provides some basis for comparison. For the near future two aspects need to be highlighted: (a) the greater use of information technology for making norm-referenced comparisons and interpretations, and (b) greater synergy between norm- and criterion-referenced decisions in all testing processes.

OBJECTIVITY

INTRODUCTION

'Objectivity' is an ambiguous term with many meanings, some of which do not even overlap. It refers to different kinds of entities and is used in various scientific disciplines. Even in psychological assessment, there are at least four different concepts of objectivity. The most important one is that of an evaluation criterion for psychological assessment instruments which stands on the same level as the two other criteria of reliability and validity. The generality of these criteria and their applicability to all assessment instruments beyond the more narrow class of psychological tests is an issue of much debate in psychological assessment.

PHILOSOPHICAL NOTIONS OF OBJECTIVITY

There are various notions of objectivity in philosophy. Gauker (1998) differentiates between the correspondence conception and the intersubjective conception of objectivity. The most important feature within the correspondence conception is mind-independence. An objective judgement is a judgement concerned with mind-independent facts which are as they are independent of what anybody may think them to be. Objectivity or objective truth in this sense is a matter of correspondence with what is out there, i.e. with a mind-independent reality. Within the intersubjective conception of objectivity, a judgement is objective if an evaluation of it as true or false may proceed without regard to the question whose judgement it is (Gauker, 1998: 161). An objective judgement in this sense expresses the consensus of rational discussants. For other notions of objectivity in philosophy see Bell (1992).

NOTIONS OF OBJECTIVITY IN PSYCHOLOGY

Many uses of the term 'objectivity' in psychology are influenced by the philosophical notions of objectivity. The standard view of scientific truth in psychology heavily borrows from the correspondence conception of objectivity. Even opponents to this view, such as, for example, constructivists and constructionists (*cf.* Gergen, 1994), construe objectivity (of knowledge) as correspondence of the cognitive-social constructions with a reality that is independent of cognition. And adherents to the related systemic approach (*cf.* Schiepek, 1986) construe objectivity (of a theory) as a naive direct representation or description of reality. Both notions are very close to the correspondence conception of objectivity. If adherents to the systemic approach construe objectivity (of propositions) as independent from the conditions of observation, the feature of mind-independence becomes obvious. From a constructivist or constructionist point of

view, the correspondence conception of objectivity is based upon an illusion. Objectivity in this sense is not attainable. This epistemological claim is transferred to the domain of psychological assessment and forms the basis on which the use of the concept of objectivity as an evaluation criterion for psychological assessment procedures is questioned (*cf.* Schiepek, 1986).

NOTIONS OF OBJECTIVITY IN PSYCHOLOGICAL ASSESSMENT

Constructivists and constructionists tend to ignore that the correspondence conception of objectivity does not play a prominent role in psychological assessment. In this domain, the intersubjective conception is much more important. Of the four different notions of objectivity, which are in the centre of discussion in psychological assessment, none is based upon the correspondence conception. Which are these notions?

The most important one emerges from psychological testing (*cf.* Walsh & Betz, 1995). Within psychological testing, objectivity (of collected, scored, and/or interpreted diagnostic findings) is construed as an evaluation criterion of psychological measurements to be ensured by the standardization of conditions (of administration, scoring, and/or interpretation of an assessment procedure). This notion of objectivity is usually at stake if the issue of objectivity is discussed in psychological assessment, especially in debates between adherents to qualitative and quantitative approaches.

Another notion of objectivity is used within item response theory. It is called specific objectivity and it refers to comparisons between persons (*cf.* McDonald, 1999: 291). If the result of a comparison between two persons is independent from the measuring instrument, i.e. the item sample used, the comparison is called specifically objective.

A third notion of objectivity goes back to Raymond B. Cattell (1986) and his followers who construe objectivity (of a psychological test) as non-transparency of the intention of assessment for the examinee. Questionnaires which are susceptible to faking good or faking bad attempts are transparent in this sense and, therefore, subjective procedures.

The fourth notion of objectivity is the most familiar one in the area of behavioural assessment (Silva, 1993) and shows the closest relations to the intersubjective conception of objectivity. In behavioural assessment objectivity (of observation) is construed as an interpersonal agreement among two or more observers who observe the same sequence of events. Sometimes, interobserver agreement is discussed within the context of the criterion of reliability (*cf.* Suen & Ary, 1989).

OBJECTIVITY AND STANDARDIZATION

The first notion of objectivity in psychological assessment explicitly acknowledges that the result of an assessment depends upon the conditions under which the assessment takes place. Since an elimination of the influences of the assessment conditions on the assessment result is impossible, a standardization of these conditions is required. Otherwise, that is the argument, it would not be possible to relate the assessment results to the single case concerned (Westmeyer, 1996: 316f.). The standardization has to apply to the three phases of administration, scoring, and interpretation of an assessment procedure (*cf.* Table 1).

Table 1 makes it very clear that the inference from the behaviour of a single case in the assessment situation to the attribute or characteristic of the single case is justified if and only if the effects of all other factors which exert their influence on the behaviour of the single case, on the scored, and on the interpreted findings, and which are mentioned as arguments of the functions f_1, f_2, and f_3, can be neglected or ignored. The problem is that there are no conditions under which this can be done. If only one single case at one point in time is considered, and that is the standard situation in the practice of psychological assessment, it is impossible to abstract from all the other factors which are of influence, apart from the attribute or characteristic of the single case to be assessed. Hence, it is not justifiable to relate the interpreted assessment data only to the single case. They cannot be constructed merely as propositions about characteristics of a single case. They have to be construed as complex, multi-placed relations, which have to take into consideration the various factors of which they depend.

Table 1. Aspects of objectivity of psychological assessment procedures

Administration
Behaviour of the single case = f_1 (attribute or characteristic of the single case concerned; other attributes or characteristics of the single case; characteristics and behaviours of the assessor; assessment technique; setting in which the assessment takes place; time of assessment; ... ; interactions between two or more of these factors)
Scoring
Scored findings = f_2 (recorded behaviour of the single case; characteristics and behaviours of the scorer; scoring technique; setting in which the scoring takes place; time of scoring; ... ; interactions between two or more of these factors)
Interpretation
Interpreted findings = f_3 (scored findings; characteristics and behaviours of the interpreter; interpretation technique; setting in which the interpretation takes place; time of interpretation; ... ; interactions between two or more of these factors)
Inference
The to be assessed attribute or characteristic of the single case concerned is usually inferred from the interpreted findings or is conceived of as identical with them.

The situation is not very different if more than one single case or one single case at more than one point in time is considered. Standardization does not mean elimination of the influences which the various factors mentioned on the right side of the equations in Table 1 exert on the results occurring on the left side. Standardization does mean trying to hold these influences constant. That is a completely different matter. Even in the case of a successful standardization of administration, scoring, and interpretation of an assessment procedure, the control of unwanted influences on the result of the intended comparison has to remain incomplete, since it is impossible to control for all interaction effects mentioned in the three equations of Table 1. Therefore, there is no fundamental difference between the situation where an assessment procedure is applied once to one single case and a situation where an assessment procedure is applied twice to one single case or once to two single cases. In each case, the results depend upon the factors listed in Table 1, and the attributes or characteristics to be assessed are only one of those.

FUTURE PERSPECTIVES AND CONCLUSIONS

In traditional approaches to psychological assessment and even within constructivist, systemic or qualitative approaches, diagnoses or case formulations as the products of assessment processes are sets of (hopefully) confirmed idiographic hypotheses referring to the single case concerned. The detailed enumeration of the circumstances and conditions under which the results have been produced are not part of the case formulation. But the idiographic hypotheses cannot stand for themselves. They have, considered by itself, no determinate or determinable empirical content. Only if they are embedded into an adequate methodological environment, which comprises all the methodical constructions to which one has to refer in the course of testing the hypotheses, is it possible to answer the question about their empirical content. The set of elements, which constitute the methodological environment, also include those factors that influence an assessment result and are listed in Table 1.

Although an idiographic hypothesis refers to a single case, the assignment of a certain empirical content to this hypothesis is always relative to the particular methodological environment into which the hypothesis is embedded. And this is not only the case for psychological assessment from a psychometric point of view, but for any kind or variant of psychological assessment. No case formulation can be regarded as adequate which does not give a detailed account of the constructions, which make up the methodological environment. Without a standardization of the administration, scoring, and interpretation of the applied assessment procedures, i.e. without satisfying the criterion of objectivity, it is hardly possible to give such an account. This underlines once again the importance of this notion of objectivity.

Increasingly becoming aware of the different notions of objectivity in psychological assessment, and the universal importance especially of the first one, may bridge the gap that still exists today between so-called quantitative and qualitative approaches, or between psychometric and systemic or constructivist ones. The criteria of objectivity, reliability, and validity, properly understood, are not confined to psychometric test procedures, but are relevant to all assessment instruments whatever their origin. Recently, a further extension of the range of applicability of this notion of objectivity has been proposed. A Task Force sponsored by the European Association of Psychological Assessment introduced, as a proposal for discussion, Guidelines for the Assessment Process (GAP) which imply, more or less, a standardization of the whole assessment process (Fernandez-Ballesteros et al., 2001). Consequently, the criterion of objectivity could not only be applied to assessment instruments, but to assessment processes as well.

RELIABILITY, VALIDITY (GENERAL), ASSESSMENT PROCESS

OBSERVATIONAL METHODS (GENERAL)

INTRODUCTION

Observational methods applied to natural or habitual contexts are scientific procedures that reveal the occurrence of perceptible behaviours, allowing them to be formally recorded and quantified. They also allow the analysis of the relations between these behaviours, such as sequentiality, association, and covariation. In many situations, observational methods are the best strategy, or even the only strategy possible (Fernández-Ballesteros, 1993): examples are the assessment of low level intervention programmes, interactions between peers, between children and adults, between the deaf and hearing, etc., social interactions at different ages, disputes between

couples or in the workplace, the behavioural repertoire of the baby, poor body posture for specific tasks, kinetic non-verbal communication (of teachers, sportsmen and women, actors and actresses, etc.), analysis of movement in multiple activities, occupation of a particular space, and the analysis of norms of socialization and desocialization.

Assessment in natural contexts through observation is unquestionably complex (Anguera, Blanco, Losada & Sánchez-Algarra, 1999). In all settings we find a range of behaviours which form a pyramid structure (Fernández del Valle & Fernández-Ballesteros, 1999). Starting from the top of the pyramid, we can break down daily life in a natural context into different levels such as family, health, school, leisure, sports, etc., revealing a tree structure with a hierarchical subdivision of situations in which behaviours that tend towards molarity interact with their natural contexts. Towards the base of the pyramid, the perceptible behaviours are increasingly molecular.

BASIC DECISIONS

Assessment in natural contexts needs a clear definition of the scope of our activity, in particular in two areas: content, and procedure or methodology.

As regards *content*, we must set the thematic limits of the specific everyday behaviour in question. There are three restrictions on the object of assessment:

(a) *Its perceptibility: total or partial.* Much has been written on perceptibility, and the positions taken have tended to depend on the psychological schools taken as a reference point. Our position is clear, in that we consider manifest behaviours – behaviours which involve total perceptibility, and which can be more reliably delimited.

(b) *The fact that it is a part of everyday life and of the natural environment of the individual.* Assessment generally focuses on habitual aspects or sectors of the life of a human being. The thousands of days and millions of hours that make up the everyday activity of an individual constitute a frame of reference that is easily wide enough for study.

(c) *Interaction with the environment.* Any behaviour needs a reference point inside its environment. For us the reference point is the molar set of the places defined in the area in which the human activities that characterize the individual's behaviour occur. Certain environments offer ideal conditions for the detection of needs: family, school, playgroups, leisure groups, etc.

(d) *Possibility of monitoring over time, as opposed to an appraisal of sporadic, chance occurrence of specific behaviours.* A dynamic approach to the study and diagnosis of human behaviour is required, imposing time limits on the interactive flow, and allowing diachronous study of certain episodes of behaviour.

From the *procedural or methodological point of view*, we should analyse why observational methods are well suited to assessment within natural contexts (Nell & Westmeyer, 1996).

Methodologically, assessment in natural contexts is particularly suited to the implementation of unobtrusive procedures to appraise the behaviour of an individual (Anguera, 1993). *Observational methodology* has both advantages and disadvantages. Amongst its advantages are its flexibility, its ability to adapt to very different behaviours and situations, its rigour in the application of the various procedural operations, and the non-restrictive and unobtrusive nature of its appraisal of real situations. Its main disadvantages are the time required, the difficulty of reducing or eliminating the reactivity bias, the complexity of the process of observer training and the restrictions imposed by ethical considerations.

DEVELOPMENT OF THE PROCESS

The process to be followed in observational methods comprises five main stages:

Correct Delimitation of the Behaviour(s) and Observation Situation

The delimitation of the subject and its contents determines to a large extent the success of the

research and facilitates the decision-making process. It is obvious that the activity has to be carefully delimited, as do the period of time, the subject(s), and the situational context. Not only does access to this information substantially improve the planning and design of the research, but the information is absolutely necessary for adapting the series of specific steps in the procedure to the contents in question. In this first phase the requirements of inter- and intra-session homogeneity must be met, because one of the most incisive criticisms of observational methods in its classical period (until the 1980s) was that the heterogeneity of different sessions or even within the same session would disqualify any possible analysis of the process under study. Likewise, this delimitation will help to eliminate biases, especially those of reactivity and expectancy.

Ad hoc Production of an Observation Tool

The extraordinary diversity of situations that can be systematically observed means that we cannot rely on standard tools, and must devote time to preparing ad hoc instruments for each study. The basic tool of observational methods is the category system, which has been progressively accompanied by the field format. The category system is more widely used due to its essential theoretical support. It is a closed system, single-coded, and non-self-adjustable, whereas field formats are especially suitable in situations of high complexity and little theoretical consistency; they are open systems, appropriate for multiple codifications, and highly self-adjustable (Anguera, 1995).

We should also mention rating scales, still occasionally used today.

Category Systems

A category system is constructed by the observer and is designed to provide a sort of *receptacle* or *mould* made of an empirical compound (reality) and a theoretical framework, to which the recorded behaviours will be assigned. Not only should the individuality of each category be studied, but the structure of the system as a whole as well.

The production process goes back and forth between reality and theory:

1. The best starting point is the production of the *repertoire* or list of features of behaviour (reality) so that it can be assumed to be *exhaustive*. This requires a large number of observation sessions. Conventional measures are used consisting of the establishment of a minimum number of successive sessions (three, four, five ...) in which no behaviours other than the ones recorded take place.
2. The next step is to propose certain conceptual criteria that allow us to group the features of behaviour according to similarity; these groups are given a provisional name.
3. Next, returning to reality, the new sessions are viewed and the behaviours of interest are assigned to the provisional groupings defined in point (2).
4. Now, from the theoretical perspective, we analyse whether the degree of homogeneity between behaviours is adequate. If necessary, some of the groups are broken down, or modified, in order to preserve (1) a conceptual differentiation between the provisional categories that we have made, (2) the possibility of assigning all the behaviours of interest to one of these categories, and (3) homogeneity between the behaviours assigned to these provisional groups.
5. Once these modifications have been made, we view new sessions, assigning the behaviours to the new categories. The process is repeated until all the categories form a system that is exhaustive within the area or situation observed and is mutually exclusive inside a particular dimension or level.

Exhaustiveness is the idea that *any* behaviour chosen from the subject's behavioural repertoire inside the environment can be assigned to one of the categories. *Mutual exclusiveness* refers to the non-overlap of the categories that comprise a system, and so each behaviour is assigned to one and only one category. However, from the point of view of the levels of interest this may not be possible – or even desirable – since very often we are interested in considering various levels of

response occurring at the same time, and so we would create multiple categories that cover all the possible combinations of the initial ones.

The categories are defined in a way that considers all their nuances, and should be accompanied by examples and counter-examples to increase their specificity.

Of course, the choice of categories can vary, and depends on who produces them. The category systems relative to a specific situation or behaviours are equivalent if during the categorization process the same criteria are adopted. However, this equivalence is a general one – not category by category, but of the whole set of categories.

Field Formats

Field formats date back to an old recording technique which has gained in consistency and is considered today as an observation tool. In the last fifteen years its development has been spectacular. Its production involves the following steps:

1 Establishing the instrument's criteria, in accordance with the objectives of the study (e.g. in the assessment of the ecological/behavioural use of the objects in the surroundings by an individual, the possible criteria would be location, verbal behaviour, activity, contact with objects, etc.).
2 List of behaviours (not closed) corresponding to each of the criteria and/or situations, recorded from the information gathered during the exploratory stage.
3 Assignation of a system of decimal coding for each of the behaviours recorded deriving from each of the criteria and which allows the use of any of them in a lower-order hierarchical system. Depending on the complexity of the case, the system may be double or triple code.
4 Production of the list of configurations. The configuration is the basic unit in the recording of field formats, and consists in linking codes corresponding to simultaneous or concurrent behaviours, which will allow an exhaustive recording of the behaviour flow, and makes subsequent data analysis considerably easier.

The configurations are based on synchronous and diachronous criteria: synchronous, because all the codes of each configuration correspond to simultaneous behaviours – one of each criterion – so that if one or more codes in a configuration are modified, this gives rise to the next. The diachronous criterion is based precisely on this succession of configurations.

The main differences between the category system (CS) and field format (FF) are shown in Table 1.

Rating Scales

This observation instrument, a dimensional recording system, is only occasionally used because of the need for an attribute or a dimension, which is not always easy or even possible.

Rating scales are lists of behaviour to which observers assign grades – usually ordinal numbers – to reflect their opinion of the intensity or degree of permanence of the behaviour.

Even when rating scales are accompanied by a correct definition in each of the estimations, the risk of subjectivity in most cases is high, because of the high level of inference that they entail. This means that these instruments must be used with great caution.

Data Collection and Optimization

The behaviour flow in any observation situation is far richer than it initially appears. Once we

Table 1. A comparison of category systems and field formats

Criterion	Category system	Field format	Advantage
Structure	Closed system	Open system	FF
Relation to theory	Theoretical framework essential	Theoretical framework recommended, not essential	CS
Dimensionality	One-dimensional	Multidimensional	FF
Codification	Single-code	Multiple-code	FF
Flexibility	Rigid system	Self-adjustable system	FF

have delimited the objective, as described previously, we now code the behaviours that interest us, after establishing the units of behaviour, and after constructing an ad hoc instrument. Nonetheless, the recording thus obtained may be low quality, for a variety of reasons: the starting criterion for the observation sessions, the choice of a particular day, the existence of periods between sessions which are not observed, whether recording during the session is continuous or interrupted, the possible lack of synchronization between observers if there are more than one, or the lack of consistency of a particular observer after recording the session, etc.

The recording must be submitted to a data quality control test which will act as a filter and will then give the observer the assurance that the data can be reliably analysed (Blanco, 1991, 1993).

Data Analysis

The data analysis should be carried out inside a specific design structure for the study in question. There are standard and non-standard designs, so named according to whether the research plan follows a pre-established design structure. The flexibility of observational methods and their specificity mean that prototype designs cannot be used; though we provide some guidelines (e.g. diachronous, synchronous, or diachronous/synchronous designs), these guidelines are by no means rigid; nonetheless, they suggest specific data analyses that are particularly well suited (Anguera, 1997).

Diachronous designs are an evaluative approach to the follow up of a unit over time. The unit may be an individual, or a small group of individuals that make up a unit. If the parameter used for the recording is frequency (i.e. extensive follow up) diachronous designs may take a variety of forms: panel analysis, regression equations, or temporal series, depending on the number of sessions recorded. In contrast, if the recording parameter is order or duration (i.e. intensive follow up) then sequential designs, through sequential analysis, can identify stable patterns of behaviour (Quera, 1993; Bakeman & Quera, 1996; Bakeman, Quera, McArthur & Robinson, 1997). These patterns may be either prospective or retrospective, and are extremely important in programme evaluation, since they provide an objective assessment of the progressive modification of the behaviour.

Synchronous designs highlight the relation between a variety of units (different individuals, or different questions to be evaluated in an individual or in a group of individuals) at a specific moment (a session). This relation is associative in symmetrical synchronous designs (log-linear analysis) and causal in asymmetrical synchronous designs (logit analysis).

Diachronous-synchronous designs – *lag-log* designs – are used in the most complex situations, corresponding to a follow up over time of a variety of units. Depending on the nature of the follow up, the various units involved, and the nature of relations between them, twenty-four different diachronous-synchronous designs can be used, thus covering all the evaluation situations of this kind.

Interpretation of the Results

The results should be interpreted in the light of the presentation of the initial problem. The results of the process on many occasions are the starting point for an intervention, or for taking decisions.

FUTURE PERSPECTIVES

The advances made in recent years clearly suggest that the short and mid term future of observational methods will be characterized by two types of development:

First, the design of *software* which will allow unlimited recording of codification, concurrence, sequentiation and temporality (Hernández-Mendo, Anguera & Bermúdez-Rivera, 2000; Hernández-Mendo, Bermúdez, Anguera & Losada, 2000; Hernández-Mendo & Anguera, in press).

Second, the systematic development of observational designs, unknown only a few years ago, that will ensure appropriate organization and analysis of the recordings.

CONCLUSIONS

We have looked at the whole process of assessment in natural contexts. As we stated in

the Introduction, assessment in natural contexts involves developing a procedure that highlights the occurrence of everyday behaviours, and allows an analysis of the relations between them. These relations can be identified objectively as a result of the analysis of data linked to the corresponding observational design. The results should be evaluated in accordance with suitable diagnostic parameters, analysing them in such a way that ensures identification of the structures of behaviour – via their different relations – underlying the perceptible behaviours so as to implement an appropriate treatment.

Countless low intensity intervention programmes and early intervention plans form part of our everyday activity; many of them pass unnoticed. There are many examples that we could mention, and in all of them the efficacy of the implementation is subject to appropriate assessment, which is based essentially on the application of observational methods.

OBSERVATIONAL TECHNIQUES IN CLINICAL SETTINGS

INTRODUCTION

This entry is written from a learning perspective that emphasizes the need to objectively evaluate behaviour as part of clinical assessment. Two practical and cost-effective techniques for obtaining behavioural samples (specimens) are discussed. The first method entails home tape recording of representative interactions. Methods of incorporating these data into treatment are discussed in addition to their assessment uses. Actigraphy is the second objective method. Behavioural measurements of waist and/or wrist activity every minute of the day and night for one, two, or more weeks can be very informative. Evidence demonstrating the desirability of obtaining behavioural measurements from children suspected of having ADHD is presented. The broader implications of these data are discussed.

OBSERVATION IN CLINICAL SETTINGS

A clinician's approach to assessment is driven either explicitly or implicitly by their theoretical orientation. I declare my theoretical orientation to contextualize this entry. I understand normal and abnormal behaviour from a parallel distributed processing (PDP) connectionist neural network (CNN) approach to learning and memory that includes both cognition and affect. Tryon (1995) has given introductory details of this position, and reasons for holding it. McLeod, Plunkett, and Rolls (1998) provide coverage that is more complete. I refer to all PDP CNN models as neural network learning theory (NNLT) because they are brain-inspired memory systems that learn from experience. Memories are learned and learning implies memory; otherwise learning would not be cumulative. Consequently, one can speak of learning and memory as interdependent facets of a single *learning-memory* process. This general approach to learning is a superset of operant and respondent conditioning that includes all forms of cognitive and emotional processing at both cortical and subcortical levels. The relevant contribution of this theoretical orientation to this entry is that experience drives the learning-memory process. Therefore, it is important for clinicians to learn as much as possible about the past and present experiences of their clients. Direct access to prior experience is not possible and therefore clinicians must rely on interview data from the client and others. We will discuss ways to make direct contact with current events.

People mainly seek professional help for behavioural and psychological problems when faced with a behavioural and/or psychological excess or deficit that persists beyond an acceptable time in themselves, their spouse, parent, child, or other family member. The clinician should first determine the frequency, intensity, and duration of these excesses and/or deficits. The clinician should then determine what triggers these excesses or deficits – what discriminative stimuli set the occasion for these excesses or deficits. The clinician also needs to determine if any social and/or other consequences currently maintain these excesses or deficits.

Clinicians can readily observe how the client behaves in session with them and with their spouse, children, and/or other family members if a joint session is held. While such observations may suggest clinical hypotheses, they constitute a small behavioural sample and are restricted to an office setting, which differs in important ways from the natural settings one wishes to generalize to. Clinicians can interview the client and other family members about behaviour that occurs outside the office but the results are frequently biased by the client's perspective. Research on eyewitness credibility clearly demonstrates that people make poor observers (Loftus & Hoffman, 1989). Psychologically distressed persons engaged in family strife are even more likely to bias reports of their behaviour and the behaviour of others. In short, one can expect widely discrepant and strongly held views of the same events across

respondents. Clinicians are frequently hard pressed to know where the truth resides. Behavioural observation is one method for obtaining the desired information. Tryon (1998) has discussed this technology. There are several reasons why clinicians do not use behavioural observation. They mainly concern difficulty and expense not covered by insurance. Observers need to be found, trained, and paid for their work which increases costs. Insurance companies may not reimburse these expenses. Observers need to visit the home and/or school, which raise logistical as well as privacy issues. More time is required to decode and analyse these data which further increases expense. The home tape recording method described in the next section is a compromise solution that offers most of the benefits of behavioural observation but is much more economical and far less invasive. It also provides opportunities for clinical intervention that might not otherwise be available.

HOME TAPE RECORDING

General Procedure

Audio tape is an inexpensive and unobtrusive technology that captures many facets of behaviour. In the days before television, people enjoyed dramatic episodes on radio because listeners readily interpreted the sound effects. The same is true for tape recordings obtained from natural settings such as the home. Much clinically rich information can be obtained by recording events in the home. Tryon (1999) has discussed this technique in greater detail than can be accomplished here and has provided background literature.

The procedure is simple. The first step is to obtain informed consent and/or ascent from those persons whose voice will be recorded. This is generally not a problem. Couples frequently present for treatment together as do families. Parents of troubled children readily understand the benefits of taping actual incidents of the behaviour they are concerned about. In general, people who seek treatment for behavioural/relational problems generally welcome the availability of first hand objective data.

The second step is to connect a high quality, preferably amplified, omnidirectional microphone to a high fidelity audio tape recorder and place it in a room where incidents of the type presented for treatment are known to occur. This frequently ends up being the breakfast or dining room table or in the living room. Audio tape equipment is among the most heavily discounted consumer products, which is what makes this technology affordable.

The third step is to collect one or more behavioural samples (specimens). This can most simply be done by inserting a 120 minute cassette and letting it play to the end, reversing the tape, and letting it play to the other end, continuously until a target event has been recorded. Recorders equipped with an auto reverse function automate this process. Alternatively, if trouble exists getting a child ready for school in the morning, then turning the recorder on before the child awakes is recommended. Likewise, the recorder can be turned on prior to other meals if conflict is expressed during lunch or dinner. It is important that tape recording begins before a critical incident occurs. It is far less helpful to turn the recorder on after an incident has begun. The objective is to record before, during, and after a target incident has resolved.

The tape is removed and another tape inserted in preparation of a second incident of the targeted problem. The second tape enables the clinician to test hypotheses formulated on the basis of the first tape. The third tape enables the clinician to replicate a previously supported hypothesis. In the case where the second tape does not replicate a hypothesis formulated from the first tape, it provides an opportunity to modify the hypothesis. The third tape provides an opportunity to test this formulation and the fourth tape provides an opportunity to replicate this reformulation. The extent to which additional tapes are needed depends largely upon what one learns from the tapes.

Clinical Intervention

Clinicians can use these tapes in at least three ways. The first method is where the client mails the tape to the clinician in advance of the next session and the clinician listens to the tape before seeing the client. Clinicians may bill for the time this takes as they are listening to the client. This procedure has the advantage of allowing the

clinician to experience the auditory stimuli associated with the events of concern to their client. Verbal behaviours are completely captured. Behaviours such as slamming doors leave clear auditory signals. Failure to respond to comments, requests, or commands is revealed by silence followed by a repetition of the verbal statement. Hearing who said what to whom augments the clinical material obtained during interview and/or testing and gives the clinician a better understanding of the relationship dynamics. How the incident began is of special interest. Who did what to whom to instigate the incident? How the incident escalates is also of special interest. Why did matters get worse? Who could have done what to resolve the problem? Did the problem escalate because of what someone did or because of what they did not do; because of what they said or did not say? The therapist can gauge the extent to which each participant's in-session presentation of prior incidents is biased towards reporting negative events. Depressed patients are especially prone to distort facts in this way. This phenomenon is generally called state-dependent (mood-congruent) recall (Matt, Vazquez & Campbell, 1992). It pertains to happy as well as sad emotions.

A second clinical method is for the client to bring the tape with them and listen to it with the therapist during the next session. If the session is just with the client, then the therapist can ask the client to narrate the events filling in any missing facts, motives, etc. The clinician can tape this session in order to record the new information provided by the client. If the session includes the husband and wife or all family members, then all participants can narrate the events. Again, it is a good idea to tape record this session. People sound different to themselves on tape because they do not also hear themselves via bone conduction. This helps provide psychological distance. Since the next session occurs several days or more after the recorded incident, this time delay provides additional psychological distance. These factors combined with the understanding that the tape captured what really happened helps people face their contribution to the relationship/behavioural problem at issue. Sometimes just the experience of hearing themselves 'misbehaving' is sufficient to stimulate critical introspection and planful change.

A third clinical option is to have couples or families review the tapes together prior to their next visit. The goal here is for them to use this technology to identify continuing and new problems and more effectively solve them without additional professional intervention.

Tryon (1996b) described a procedure for diagnosing, categorizing, reinforcement contingencies that can maintain behavioural excesses and deficits. Home tape recording can facilitate this process through either informal or formal methods. A primary value of this system is that assessment and behavioural diagnosis lead prescriptively to intervention.

ACTIGRAPHY

Forty-eight DSM-IV disorders cite psychomotor retardation or agitation, or sleep disorder, that is detectable through movement as part of their formal inclusion or exclusion criteria (Tryon, 2001). Tryon (1996a) reviewed the literature and reported that validity coefficient of actigraphy against polysomnography ranged from 0.49 to 0.98 with most validity coefficients in the 0.80s and 0.90s. These behaviours mainly occur outside of the session and are therefore not directly observable by the clinician. An increasing diversity of actigraphs are available that can measure and record activity levels 24 hours a day for several weeks (Montoye, Kemper, Saris & Washburn, 1996; Tryon, 1991; Tryon & Williams, 1996; U.S. Department of Health and Human Services, 1996).

The DSM is trait oriented in that the behaviours described in the inclusion and exclusion criteria are assumed to persist for at least two weeks in order to make a diagnosis. These are not transient conditions. The clinician consults with parents, family members, teachers, and others to learn more about behaviour that they cannot directly observe. Actigraphy provides an objective method for measuring behaviour over weeks and months as necessary in order to make more informed diagnostic decisions and in order to evaluate the effects of treatment. Actigraphs (Tryon, 1991; Tryon & Williams, 1996) are most frequently attached to the waist and/or wrist. The waist is best for measuring energy intensive movements. When the waist moves independent observers will

likely also note movement. The wrist has been the preferred site of attachment for sleep studies as this body site moves most frequently while awake.

Attention Deficit Hyperactivity Disorder (ADHD) is the most frequently diagnosed behaviour disorder in children affecting approximately 3 to 5% of school-aged children (National Institutes of Health, 2000). Reports by teachers and parents form an important basis of these diagnoses. Tryon and Pinto (1994) demonstrate the need for objective data when making judgements about activity level. This example is intended to make the general case for measuring activity level when pertinent diagnostic questions arise. The Hyperactivity Scale IV of the Conners Teacher Rating Scale (CTRS: Conners, 1973) was administered to 450 boys from six parochial schools from grades 1 to 6. Norms developed by Goyette, Conners, and Ulrich (1978) were used to assign boys to one of three groups. The 22 boys who scored two or more standard deviations above the normative mean were classified as 'clinically' hyperactive. The seven boys who scored from 1 to 1.99 standard deviations above the normative mean were classified as 'mildly' hyperactive. A random sample of 31 boys from the remaining children who scored less than one standard deviation above the mean were classified as 'normally' active. All 60 of these children were rated on the Motor Excess subscale of the Revised Behaviour Problem Checklist (RBPC: Lahey & Piacentini, 1985) and the Nervous–Overactive subscale of the Teacher Report Form (TRF: Achenbach & Edelbrock, 1986) by the same teacher who rated them with the CTRS. No child was on medication. All three teacher rating scales were strongly intercorrelated: CTRS and RBPC, $r(58) = 0.89$, $p < 0.001$; CTRS and TRF, $r(58) = 0.79$, $p < 0.001$; RBPC and TRF, $r(58) = 0.79$, $p < 0.001$.

Digital step counters (Free Style USA from L. L. Bean, Inc.) were worn by all 60 children at the waist in school and at home, from the time they got up until they went to bed, for 14 consecutive days. Parents recorded wearing time. Activity was expressed as steps per hour of wearing time. The means (and standard deviations) of activity measures were as follows: normal = 283.28 (139.41), mild = 500.83 (241.54), and clinical = 816.86 (799.04). First week activity measures correlated $r(58) = 0.46$, $p = 0.01$ with CTRS, $r(58) = 0.44$, $p < 0.01$ with RBPC, and $r(58) = 0.32$, $p < 0.05$ with TRF. Second week activity measures correlated $r(58) = 0.55$, $p < 0.01$ with CTRS, $r(58) = 0.58$, $p < 0.01$ with RBPC, and $r(58) = 0.44$, $p < 0.01$ with TRF. These data all seem to strongly support the contemporary practice of basing clinical diagnosis of ADHD partially on teacher ratings. However, sorting subjects within each of the three groups by activity level and plotting all three groups of subjects on the same graph revealed that the most active normal subject was level with the 15th most active child in the 'clinical' group. Put otherwise, 15 of the 22 children rated as 'clinically' hyperactive on the CTRS took no more steps per hour than the most active child rated as 'normal'. If all children rated as clinically hyperactive by teachers had been medicated to control hyperactivity, a not unlikely event, then the error rate would have been $15/22 = 0.68 = 68\%$. The possibility of incorrectly identifying motor excess in two-thirds of children rated clinically hyperactive by teachers is a serious clinical problem. Objective data are clearly indicated and can be obtained in various cost-effective ways as mentioned above (Tryon & Pinto 1994).

Activity norms do not exist. Clinicians therefore need to obtain activity measurements from control children who are of the same age, sex, and preferably in the same classes and after school activities as the target child. At least a one-week and preferably a two-week behavioural sample should be taken in order to replicate each day of the week once. Behavioural assessment can be continued during pharmacological and/or behavioural treatment in order to document change or the lack thereof with regard to activity level. It is not necessary to continue to monitor control children. Their two-week behavioural sample can be used as the target values which treatment should aim towards if it seeks to normalize the activity level of the targeted ADHD child. This establishes an ecologically valid treatment criterion as opposed to settling for statistically significant decreases that may not be practically meaningful.

FUTURE PERSPECTIVES

Both methods of data collection discussed above use technology to inform clinicians about client

behaviours that take place outside of the session. Technology continues to develop and will provide additional opportunities through time. Newer actigraphs are currently available that can record activity every minute of the day and night for 88 consecutive days. Other actigraphs estimate caloric expenditure from waist activity and assist the wearer to reduce their body weight through increased activity. Some actigraphs measure ambient light intensity. GPS receivers can be used to track where a person is at all times of the day and night. Heart rate can also be digitally recorded in the field. Small web cameras and the Internet can enable password protected observation in the home and elsewhere. Feedback actigraphs are being developed to help hyperactive children better regulate their behaviour. These devices can readily be integrated into reinforcement programmes to enhance children's motivation for compliance. Other technological advances are expected.

It is presently easier to collect than to analyse activity data. Many statistical methods for analysing these data are available but consensus has yet to be reached regarding which methods are to be preferred. This is a broad and wide-open area for future research.

CONCLUSIONS

Research has demonstrated that many people do not accurately recall past events especially when they are emotionally distressed. Tape recordings capture speech and the auditory consequences of behaviour such as door slamming. Audio taping can reveal important interpersonal–family dynamics. It can also focus therapy in productive ways described above.

People cannot accurately quantify their activity level and would not be willing to do so even if they could every minute, or every 15 or 30 minutes of the day let alone the night. Yet, this information is relevant to 48 DSM-IV diagnostic categories. Actigraphy entails unobtrusive methods for obtaining high quality time series activity measurements. It should be used in all situations where motor excess or deficits impact clinical diagnosis to avoid problems such as the one described. Actigraphy should also be used to evaluate treatment effects or the lack thereof.

Both home tape recording and actigraphy entail the collection of what I call 'behavioural specimens' that can subsequently be analysed in various ways. They provide an objective record of events that can be compared to the client's perceptions, if desired, or used to the understand and evaluate clinical conditions. I believe that both home tape recording and actigraphy are important to behavioural assessment and clinical practice.

OBSERVATIONAL TECHNIQUES IN WORK AND ORGANIZATIONAL SETTINGS

INTRODUCTION

The assessment of observable human behaviour is one of the core problems of Work and Organizational Psychology. Beginning in its early history the discipline applied measurement and observational techniques of experimental psychology by simulating concrete work settings and tasks and assessing reaction times, for example, of tram drivers or aircraft pilots. Even before the growth of radical Behaviourism, it was influenced by the time and motion studies of Frederic W. Taylor's Scientific Management. Blum and Naylor (1968: 174) in their classical textbook emphasized the importance of the development of observable criteria: 'The criterion is basic to all measurement in industrial psychology. To overstate its importance would be literally impossible. Without adequate criteria, industrial psychology is ineffective and ceases to be a science. In other words, the magnitude of the contribution of industrial psychology is *completely* determined by the adequacy of the criterion measures evolved.'

FIELDS AND LEVELS

Observational techniques for the assessment of human behaviour can be found in all fields of modern Work and Organizational Psychology, for example in:

1 Human–Computer Interaction
2 Task and job analysis
3 Performance appraisal
4 Leadership behaviour and work activity of managers
5 Performance in Assessment Centres
6 Customer service behaviour
7 Team performance
8 Productivity measurement of organizational behaviour

Most observational techniques have been developed at the individual level. Micro-processes, movements of keystrokes and reaction times by milliseconds are studied in the field of Human–Computer Interaction. Observational techniques applied to job analyses, or Assessment Centres (AC), also focus on the

behaviour of the individuals; however, they embrace longer series of actions or a broader set of criteria. The observer tries to assess all possible criteria, which are assumed important for the job.

The next level is the assessment of interactions between two and more people. However, observation techniques in the field often neglect that human behaviour results from an interaction process. For example, it is typical for leaderless group discussion observations in ACs to rate the performance of all individual group members by trained observers. The same applies to observational techniques of co-operative leadership behaviour and work activity lists of managers, or ratings of the friendliness of service persons interacting with 'mystery customers'. The influence of the behaviour of the interacting persons can be ignored only if they show a highly standardized behaviour – as perhaps in the case of trained mystery customers. Standardizing interaction behaviour is difficult. People with different cultural backgrounds interpret the same standard behaviour differently. In studies of intercultural interactions, it is necessary to analyse the social situation, interaction history, and intercultural meaning of the social and behavioural context and to develop special instruments for the assessment of the interactions in different cultures or intercultural teams (Smith & Bond, 1998).

Interrelated groups are units of social systems called organizations. The organization therefore forms the last level of assessment in work and organizational settings. Typical criteria are absence rate, productivity of the organization, or market share and return on investments.

It is important to decide which level of observation or unit to use and which will result in the most useful information. It is possible to assess criteria of the individual, group, and criteria of overall organizational level behaviour as well. Von Cranach (1996) and McGrath and Tschan (2001) developed a group action and multilevel organization or complex systems theory and favour multilevel analysis. They assume that human actions are always organized on many levels (individual and several social systems levels) that are interrelated. Each level mirrors specific behaviour attributes and influences, but more research is necessary to explore the differences and relations.

Below we will concentrate on a short description of illustrative examples of psychological techniques but will also mention and discuss similar techniques of the neighbouring disciplines.

EXAMPLES OF OBSERVATIONAL TECHNIQUES

For nearly 100 years, engineers and social scientists have applied behaviour observation techniques in time and motion studies. They are based on classification systems of observable motion units (for example 'move hand to target', 'grasp target by fingers'). The observation protocol records the sequence and time of the motions observed. The purpose of the assessment is to identify the 'best-way' (normally the shortest sequence of motions) and take it as a model for training and for the definition of standard operation time.

In the field of Human–Computer Interaction, researchers began by rediscovering these techniques and enthusiastically assessed and collected lots of behavioural data by automatic log file protocols of the computer systems and constructing 'best-way models' for software design and the training of novices. However, humans are different and their behaviour can be easily misinterpreted. Therefore, behaviour protocol data today is not interpreted without additional data from thinking-aloud techniques and interviews. The 'Heterarchic Task Analysis' (Greif, 1991) is an illustrative example of perhaps the most intensive micro-process analysis in the field. It integrates observation of keystroke behaviour (by log files), video records (up to three cameras and split screen presentation) and video-confrontation interview. Similar techniques are applied to analyse the interaction process of the customer when using the Internet services of electronic business firms.

Efficient and adaptive human task performance nearly always demands cognitive information processing. Since these processes are unobservable for most assessment instruments of processes, tasks or jobs it is preferred to apply a combination of observation and interview, called observation-interviews. The assessment of human behaviour by a typical job analysis instrument is normally performed in a sequence. It starts with a listing of the tasks and a description of typical sequences by a semi-standardized interview. The second step is

an observation period (one to four hours). It ends with a scaling of a set of items describing 'normal' job behaviour (the interviewer normally gives the ratings). Based on multiple factor analysis or theory oriented clustering of the items, the authors of the instruments offer a tabulation of the item values and an assessment of general job dimensions. Typical job demand dimensions are job complexity, variability and decision latitude, or in the field of stress, time pressure, daily hassles, and social stress (e.g. by conflicts). The assessment can give useful information for the construction of personnel selection and performance appraisal instruments, wage groups, and training programmes. Modern performance appraisal techniques apply a variety of scaling methods, like Behaviourally Anchored Rating Scales (BARS, Smith & Kendall, 1963).

Pritchard (1990) developed a complex scaling approach of the productivity, effectiveness, and overall individual, group and organization performance, called Productivity Measurement and Enhancement System (Promes). A design team develops quantitative, behaviourally related measurement criteria based on a task analysis and agreement on the overall objectives of the units. For all measures of the units, a (linear or curvilinear) function is constructed which shows how much contribution is being made to the overall organizational productivity by each level of the scaling values. Based on the system, regular written reports are given to unit personnel and managers and a feedback system for the employees is implemented. Long-term studies of the application of Promes and performance feedback systems show a very strong improvement and large effect size of overall organizational criteria of productivity.

FUTURE PERSPECTIVES AND CONCLUSIONS

The service of modern consultancies is based on the analysis and comparison of economic data. More and more, they advance to the assessment of human performance ratings. However, they seem to prefer expert interviews or questionnaires, constructed without any control of the reliability of the scales or validation of their assumed relationship to observable behavioural measures. This seems to be a pragmatic solution, which is much less time-consuming. However, since the reliability and validity of this data is unknown, the usefulness of the resulting conclusions is questionable. Psychological assessment techniques in the field sometimes may be impracticable. Evaluation studies are necessary which test the validity of simple expert rating techniques or 'light versions' of the complex techniques mentioned above. However, the study of human behaviour in work organizations and organization settings in itself is a complex problem and therefore will always challenge extensive psychological theorizing and measurement technologies.

OPTIMISM

INTRODUCTION

In this entry, we review approaches to the measurement of optimism and the closely related construct of hope. Emphasis is placed on existing measures, but we also discuss assessment issues to be addressed in future research.

ETYMOLOGICAL HISTORY OF OPTIMISM AND HOPE

The term *optimism* and its ostensible cousin *pessimism* are relatively recent arrivals on the historical scene (Siçinski, 1972). In the 1700s, Leibniz characterized optimism as a mode of thinking, and Voltaire popularized the term in his 1759 novel *Candide*, which was critical of the apparent shallowness of optimism. Pessimism appeared a century later, independently introduced by Schopenhauer and Coleridge.

In their original forms, optimism and pessimism were not symmetric. Optimism as discussed by Leibniz was cognitive, reflecting a judgement that good would predominate over evil, even if goodness entailed suffering. In contrast, pessimism as discussed by Schopenhauer was emotional: the pessimistic individual was one for whom suffering would outweigh happiness. Note that someone can be optimistic in the cognitive–Leibniz sense yet pessimistic in the emotional–Schopenhauer sense.

The term *hope* shares with optimism and pessimism an orientation towards future events and experiences but has a much longer history. Along with faith and charity, hope was a chief virtue in Judaeo-Christian discourse. Hope referred to positive expectations about matters with a reasonable likelihood of coming to pass. Over time, hope (and hopelessness) became entwined with optimism (and pessimism). The connotations of each concept spilled over into the others.

Contemporary approaches to hope and optimism thus share three features. First, both refer to a future-minded stance blending thought and feeling. This stance is a belief that in the future, good events and associated positive feelings will be more likely than bad events and associated negative feelings. Second, akin to their original meanings, hope and optimism are somewhat grounded in reality – they are illusions perhaps, but not delusions. Third, optimism and hope entail beliefs about agency: the individual can act to make good events more likely and bad events less likely.

PSYCHOLOGICAL APPROACHES TO OPTIMISM AND HOPE

Some writers – usually social philosophers – treat hope and optimism as features of general human nature to be praised or decried. In contrast, others – usually research-minded psychologists in the personality or clinical tradition – regard hope and optimism as characteristics that people possess to varying degrees. Three research streams define this latter approach. Each line of work has an associated self-report measure, has focused on the consequences of the individual difference as opposed to the antecedents, and has spawned a large literature demonstrating that hope and optimism (or at least the absence of their opposites) are associated with desirable outcomes like positive mood and good morale, perseverance, effective problem solving, popularity, good health, long life, freedom from trauma, and success in academic, athletic, military, occupational, and political domains.

First, Scheier and Carver (1985) studied a personality variable they identify as *dispositional optimism*: the global expectation that good things will be plentiful and bad things scarce in the future. Scheier and Carver's perspective is that all realms of human behaviour entail the identification and adoption of goals and the regulation of actions vis-à-vis these goals. In this self-regulatory model, optimism refers to how people perceive impediments to their goals. In the face of difficulties, do

people believe that goals will be achieved? If so, they are optimistic – if not, they are pessimistic. Optimism leads to efforts to attain the goal, whereas pessimism leads to giving up.

Second, Seligman and his colleagues approached optimism in terms of *explanatory styles* – how individuals characteristically explain the causes of bad events (Buchanan & Seligman, 1995). Based upon the attributional reformulation of the learned helplessness model (Abramson, Seligman & Teasdale, 1978), this approach suggests that those who explain bad events using external, unstable, and specific causes are optimistic, whereas those who favour internal, stable, and global causes are pessimistic. The original helplessness model proposed that following uncontrollable aversive events, animals and people become helpless – passive and unresponsive – presumably because they have learned that there is no contingency between actions and outcomes. This generalized learning that actions are unrelated to outcomes produces later helplessness. As predicted, explanatory style is correlated with outcomes such as depression, illness, and failure.

Third, Snyder (2000) defined *hope* as the expectation that one's goals can be achieved. According to Snyder, goal-directed expectations are composed of two separate components. The first is agency, or one's determination to achieve goals. The second is pathways, or one's beliefs that successful plans can be generated to reach goals.

MEASURES OF OPTIMISM AND HOPE

As individual differences, optimism and hope (and/or pessimism and hopelessness) have over the years inspired several dozen measures. Most have been self-report questionnaires, although researchers have also employed interviews, observer reports, or content analyses. In addition, an optimism subscale composed of MMPI or MMPI-2 items allows archived MMPI protocols to be rescored after the fact (Malinchoc, Offord & Colligan, 1995).

In the case of explanatory style and hope, there are self-report measures for children and adults, as well as content analysis strategies for scoring these characteristics from written or spoken material (see Lopez, Ciarlelli, Coffman, Stone & Wyatt, 2000; Reivich, 1995). Although dispositional optimism has not been assessed among younger individuals, the straight-forwardness of the self-report measure implies its suitability for early teens or even children. Hope can also be assessed by observer-reports and interviews. There are also various domain-specific versions of hope and explanatory styles (e.g. hope concerning family life; explanatory style for academics).

As noted, each of the well-known contemporary research traditions has been facilitated by reliable and valid measures. The most important of these are summarized in Table 1. Convergence among the different measures of hope and optimism has not been the subject of much research, although the occasional study finds a modicum of agreement.

FUTURE DIRECTIONS

Several issues relevant to the assessment of optimism and hope need further scrutiny.

Tonic versus Phasic Assessment

One criticism of personality assessment is that typical measures ignore whether a given personality characteristic is *tonic* (constant) or *phasic* (waxing and waning according to its use). Are there settings or situations in which an individual difference characteristic allows one to 'rise to the occasion' (or not)? Hope and optimism are usually measured as if they were tonic, but they seem especially pertinent at times of potential transition or when personally relevant outcomes loom. Perhaps the best way to measure hope and optimism is at these occasions.

Cross-Cultural Assessment

Researchers have begun translating measures of optimism and hope and administering them around the world (e.g. Lee & Seligman, 1997). Two conclusions sum up most existing research: (i) people in different cultures sometimes show mean differences that are readily interpretable along cultural dimensions (e.g. people in collectivist Asian cultures have a less optimistic explanatory style than their individualistic Western

Table 1. Major measures of optimism and hope

Revised Life Orientation Test (LOT-R; Scheier, Carver & Bridges, 1994)
- self-report questionnaire composed of eight items (two fillers) reflecting optimism or pessimism which the respondent rates in terms of endorsement on 0–4 scales
- internal reliability (alpha coefficients): ~0.80
- test–retest reliability: ~0.60–0.80
- construct validity: correlates 0.30 with active coping and 0.50 with coping by positive reframing, even when controlling for neuroticism and self-esteem

Attributional Style Questionnaire (ASQ; Peterson et al., 1982)
- self-report questionnaire composed of six good events and six bad events for which respondent writes 'one major cause' and then rates each cause on 1–7 point scales according to its internality, stability, and globality
- internal reliability (alpha coefficients): 0.40–0.60 for individual dimensions; 0.70 for composites
- test–retest reliability: 0.50–0.60 for individual dimensions; 0.70 for composites
- construct validity: correlates ~0.25 with various indices of helpless behaviour: depressive symptoms, academic failure, morbidity, and so on

Hope Scale (Snyder et al., 1996)
- self-report questionnaire composed of twelve items (four fillers) reflecting agency or pathways, which respondent rates in terms of endorsement on 1–4 point scales
- internal reliability (alpha coefficients): ~0.80
- test–retest reliability: ~0.80
- construct validity: correlates –0.50 with hopelessness scale, and –0.40 with depressive symptoms

counterparts), and (ii) the correlates of hope and optimism are nonetheless similar across cultures. For future research, we suggest doing more than just comparing and contrasting mean scores across samples. The causes and correlates of hope and optimism may differ across cultures in accordance with cultural features such as prevailing religious ideology.

Assessment of Collective Optimism and Hope

In everyday use, optimism and hope are terms often applied to collectivities: families, groups, and organizations, even entire nations and cultures. Yet, psychologically oriented researchers have been slow to study what can be termed *collective optimism* or *collective hope*, and most studies to date have been at the individual level. We suggest that future researchers grapple with how to assess optimism and hope as group properties, following the lead of investigators of collective efficacy (e.g. Zaccaro, Blair, Peterson & Zazanis, 1995). We are not calling for the reinvention of the group mind but simply recognizing that members of a collectivity share optimistic or pessimistic beliefs about their group and its future.

Collective optimism and pessimism can of course be assessed by averaging individual-level scores of group members, but a more interesting strategy is to look at products of the collectivity: religious texts, political platforms, popular songs, grade school primers, newspaper stories, and the like. To be sure, most of these products are created by individuals, but to the degree that they become widely endorsed by the collectivity, we can speak of them as a statement by that collectivity about how it regards itself and its future. Content analysis strategies developed to score individual-level products (e.g. letters, psychotherapy transcripts) can be applied to collectivity-level products. For example, we have scored the optimism versus pessimism evident in annual reports by corporations to stockholders, finding that more optimistic accounts predict higher stock prices one year later (Lee, Peterson, Wang & Gillespie, 2000).

FUTURE PERSPECTIVES AND CONCLUSIONS

The constructs of hope and optimism are of great interest to contemporary psychologists. The research literature to date is fragmented because of the existence of different measures which – perhaps – tape somewhat different aspects of these constructs. Thus, the most immediate goal for future research should be the development of a single measure of optimism and hope that

captures all of their features: positive expectation, positive emotion, positive motivation (agency), and positive behaviour (pathways). This composite measure should further try to gauge whether one's optimism and hope are realistic.

ORGANIZATIONAL CULTURE

INTRODUCTION

While research of corporate/organizational 'climate' looks at the link between individuals, groups, and performance experienced on a daily basis (e.g. communication, networking, reward systems, leadership styles), the term 'organizational culture' refers to the context in which these events occur.

Organizational culture (OC) is what a group learns over a period of time as it solves its problem of survival in an external environment and internal integration (Schein, 1990). Schein points out three areas where culture manifests itself: observable artefacts, values/norms, and basic underlying assumptions to which most researchers refer to. OC supports effective control (to regulate behaviour), normative order (to guide

behaviour), promotion of innovation (in a culture that encourages creative thinking), strategy formulation, and employee commitment. Sackmann, Phillips, Kleinberg, and Boyacigiller (1997) suggest in that respect that cultural context contains greater regional, national, industry and regional level, and within the organization a functional, hierarchy and tenure level, that are influenced by gender, profession, ethnicity and religion.

Another aspect of OC highlights how well an individual fits an organizational context (O'Reilly, Chatmann & Caldwell, 1991). In this regard values and expectations of individuals interact with facets of the situation (e.g. incentive systems, norms) to affect the individual's attitudinal and behavioural responses. Furthermore OC-concepts guide OD and Change Management activities. The sustained interest in OC throughout the past decade has confirmed that, in order to understand and change an organization, a researcher must examine the linkages between underlying values, organizational structures, and individual meaning (Denison & Spreitzer, 1991).

In regard to the assessment of OC it is challenging that values/norms and basic assumptions influence behaviour on a subconscious level and are therefore not directly accessible for questioning or observation. Even the examination of artefacts and their meaning remains at first on a descriptive level (e.g. in the form of typologies), because terms of measurement and correlations have not been established yet.

CULTURE AS INTERNAL AND AS EXTERNAL VARIABLE; AND AS ROOT METAPHOR

Smircich (1983) distinguishes between cultures either as an independent (external) variable (like the culture of a nation), as a dependent (internal) variable (like corporate culture), or as a root metaphor for conceptualizing organization.

Culture as an *External* Variable

Culture as an external variable refers to the specific culture of a country influencing organizations. This specific culture is brought into the organization by leadership practices (e.g. commitment to employees, collective decision making) and leads to comparative management studies that investigate, e.g., variations in management styles, employee practices, and attitudes across countries, e.g. Japanese and American (Ouchi, 1981).

Instruments to assess culture as an external variable include the following. Hofstede (1994) tried to determine empirically the main criteria by which national cultures differ, by using his *Values Survey Module* ((VSM) 1994 IRIC; see Table 1). He distinguishes *Power Distance*, *Uncertainty Avoidance, Individualism–Collectivism*, and *Masculinity–Femininity*. The four value framework which was later expanded to five values (long-term-orientation) has had quite an impact not only on researchers but also on the way cross-country comparisons or value profiles were generated (Spector, Cooper & Sparks, 2001). However, Spector et al. (2001) recently showed that internal consistency (coefficient α) statistics from samples representing 23 nation/provinces tended to be poor and mainly failed to achieve a criterion of 0.60. Even when data were aggregated by samples, coefficient αs were poor for all but long-term orientation. A replication of Hofstede's ecological factor analysis (from 1994) failed to support the five subscales. Spector et al. (2001) suggest that the construct validity of these scales is suspect, and that they should be used with caution.

In reference to Hofstede (1994), one needs to closely examine the selection and meaning of the four, later five, dimensions. It is suggested by Strohschneider (2001) that there might be several more cultural aspects than originally found by Hofstede, i.e. religious assumptions about mankind or approaches to problem solving. Because of the low reliability of the test, one might also conclude that the representatives of the different cultures addressed the specific items in a quite differentiated manner. It seems that the closeness of each dimension was not apparent.

Culture as an *Internal* Variable

The term OC as an internal variable acknowledges that organizations themselves are culture-producing phenomena. Similar to the researchers of culture as an external variable early research activities like Deal and Kennedy's (1982) lead to types of Organizations that ought to be typical for success, e.g. tough-guy macho (e.g. Media and Computer Companies); work hard, play hard

Table 1. Instrument to assess organizational culture in chronological order

Culture as an **external** variable			
Hofstede (1998; IRIC, 1994) Values Survey Module (VSM)	National *Values* Large vs. small power distance Strong vs. weak uncertainty avoidance Individualism vs. collectivism Masculinity vs. femininity Long- vs. short-term orientation	Spector et al.'s (2001) replication: Cronbach's α: −0.46 to 0.57, only acceptable for long-term orientation (0.74)	Validity: No information found
Culture as an **internal** variable			
Kilman and Saxton (1983) Culture Gap Survey (CGS)	*Behavioural norms* Technical/Human concern Short-term/long-term orientation Task support, Task innovation Social relations, Personal freedom	Retest reliability: 0.83–0.94 Cronbach's α: 0.60 (personal freedom)–0.86 (technical concern) in a study by Xenikou and Furnham (1996)	Validity: No information found
Glaser (1983) Corporate Culture Survey (CCS)	Intends to measure *values* and holds four subscales: Values, Heroes/heroines, Traditions/rituals Cultural network	Cronbach's α: 0.55 (rituals)– 0.77 (heroes) in a study by Xenikou and Furnham (1996)	Validity: No information found
Sashkin (1984) Organizational Beliefs Questionnaires (OBQ)	Ten subscales of *values*: Work should be fun Being the best Innovation Attention to detail Work and value of people Quality Communicating to get the job done Growth/profit/other indicators of success Hands-on-management Importance of a shared philosophy	Cronbach's α: 0.35 (quality)– 0.76 (communication) in a study by Xenikou and Furnham (1996)	Validity: No information found
Schriber and Gutek (1987) Time-at-work	Temporal Dimensions of *Norms* Schedules and deadlines Punctuality Future orientation Time boundaries between work and non-work Quality vs. speed Synchronization of work with others through time Awareness of time use Work pace Allocation of time Sequencing of tasks through time Intraorganizational time boundaries Autonomy of time use Variety vs. routine	Cronbach's α range from 0.52 (variety vs. routine) to 0.80 (schedules and deadlines)	Principal component analysis

(*continued*)

Table 1. Continued

O'Reilly, Chatmann, and Caldwell (1991) Organizational Culture Profile (OCP)	*Values* Innovation Stability People orientation Outcome orientation Easygoingness Detail orientation Team orientation	No reliability information found in cited article	Principal component analysis
Quinn and Spreitzer (1991) Culture scales based on CVM Institutional Performance Survey (IPS, Zammunto & Krakower, 1991)	*Values* Group Culture Developmental Culture Hierachical Culture Rational Culture	Cronbach's α: for IPS 0.71 (Rational Culture)–0.79 (Developmental Culture); for Likert scales: 0.77 (Hierarchical Culture) to 0.84 (Group Culture)	Multitrait multimethod analysis convergent validity: 0.212 to 0.513; discriminant validity: W=0.7643**
Cooke and Szumal (1993) Organizational Culture Inventory (OCI)	*Normative beliefs*: Constructive norms (achievement, self-actualizing, humanistic encouraging, affiliative) Passive-Defensive norms (approval, conventional, dependent, avoidance) Aggressive-Defensive norms (oppositional, power, competitive, perfectionistic)	Conbach's α range from 0.67 to 0.92 Interrater: 0.88 to 0.93	Construct validity: a three-factor solution accounts for 65% of variance
Denison and Mishra (1995) Culture Traits Survey	*Culture 'Traits'*: Involvement (Input, Collaboration) Consistency (Agreement, Predictability) Adaptability (Change, Responsiveness) Mission (Direction, Mission)	Cronbach's α range from 0.63 (Adaptability) to 0.81 (Mission)	Correlations for: return on assets and sales growth

Chatmann and Jehn (1994) using the Organizational Culture Profile (OCP, by O'Reilly et al., 1991)	*Values* Innovation Stability People orientation Outcome orientation Easygoingness Detail orientation Team orientation (Q-sorting 54 values into nine categories ranging from 'most characteristic of my firm's culture' to 'most uncharacteristic')	Retest Reliability: range from 0.65 to 0.87	Principal component analysis reveal 7 factors
Howard (1998) Competing Values Model (CVM)	Two primary *value* dimensions: Structural control vs. flexibilty and internal focus vs. external focus Result in: Human relations (Supportiveness, Team orientation) Open systems (Innovation, External legitimy, Aggressiveness) Internal process (Stability, Control) Rational goal (Attention to detail, Outcome orientation) Q-sort and MDS with 54 OCP items	70% interrater agreement	Non-metric scaling
Bluedorn, Kalliath, Strube, and Martin (1999) Inventory of Polychronic Values (IPV)	*Values* Polychronicity (= extent to which people in a culture prefer to be engaged in two or more tasks or events simultaneously, and believe their preference is the best way to do things)	Cronbach's α 0.80 (1. sample)–0.86 (2. sample)	Principal component analysis revealed ten items loading on a single factor Retest correlations range from 0.78 (four week interval) to 0.95 (immediate retest) Content adequacy via Q-sort approach

(e.g. Car Distributors, Retail Sales); bet your company (e.g. Aerospace, Oil, Capital goods); and process culture (e.g. Banking, Pharmaceuticals, Public utilities). In that respect, the Corporate Culture Survey (CCS, Glaser, 1983) consists of 20 items to measure values based on Deal and Kennedy's description of culture types.

Peters and Waterman (1982) on the other hand tried to identify cultural factors of management practices (e.g. bias to action, closeness to the customer). The current research emphasizes internal factors of OC as they seem to influence aspects of change and development in organizations strongly.

Culture as an Internal Variable: Instruments for Assessment

To measure culture as internal variable standard questionnaires about organizational norms or beliefs (e.g. Bernstein & Burke, 1989) or cultural inventories (e.g. Denison, 1996; see Table 1) were developed to allow interorganizational comparison. Most authors believe that although at the beginning of OC research the goal has been 'thick description' relying on qualitative methods such as in-depth, open-ended interviewing and ethnographic observation, these approaches have been bought at a cost: analytic comparison across organizations remain difficult.

Among the most extensively tested and validated instruments are two designed to measure the cultural variations identified in the Competing Values Model (CVM, Denison & Spreitzer, 1991; Zammunto & Krakower, 1991). According to this model, values and assumptions vary along two main dimensions: focus on internal maintenance versus focus on external, competitive position; and emphasis on stability, control, and order versus emphasis on change and flexibility. Cross-tabulating the two dimensions creates a typology of ideal types: the team, the adhocracy, the hierarchy, and the firm. The CVM framework is supposed to be a metatheory, originally developed to explain differences in values underlying various organizational effectiveness models.

Two instruments relying on the CVM are presented by Quinn and Spreitzer (1991). The first instrument, called Institutional Performance Survey (IPS, Zammunto & Krakower, 1991), uses four scenarios to describe each of the four quadrants in the CVM. Respondents are asked to divide 100 points among the four scenarios in the question, depending on how similar they think each scenario is to their own OC (Cronbach's α: 0.71 to 0.79). The second instrument is contrasted with the IPS in that it is designed to use Likert scales, which enable independent measures of each culture quadrant (Cronbach's α: 0.77 to 0.84). Factor analysis provides additional support for the structure of these measures as independent indicators. Also Howard (1998) used the CVM as the underlying model to analyse OC in combination with the Q-sort technique described below.

The Culture Gap Survey (CGS, Kilman & Saxton, 1983) was developed to measure behavioural norms with four subscales reflecting 2×2 framework (technical/human concern and short-long-term orientation). They assessed norms through closed-ended items contained in a standardized questionnaire. The questions are designed to yield four scales covering norms about task support, task innovation, social relationships, and personal freedom. The Organizational Culture Profile (OCP, O'Reilly et al., 1991; Howard, 1998; Chatmann & Jehn, 1994) contains 54 value statements that can generically capture individual and organizational values. Following the general procedure of generating Q-sort profiles, respondents sort 54 items into nine categories, ranging, e.g., from most to least characteristic. Results of the principal factor analysis showed that OC can be characterized by (1) innovation and risk taking, (2) attention to detail, (3) orientation towards outcomes or results, (4) aggressiveness and competitiveness, (5) supportiveness, (6) emphasis in growth and rewards, (7) a collaborative and team orientation, (8) and decisiveness (O'Reilly et al., 1991).

The Inventory of Polychronic Values (IPV, Bluedorn et al., 1999) is a psychometric measure of polychronicity, that means the extent to which people in a culture prefer to be engaged in two or more tasks or events simultaneously (and believe their preference is the best way to do things). Similar to the IPV, the 'Time-at-work' questionnaire (Schriber & Gutek, 1987) is designed to assess various possible temporal dimensions of work organizations, e.g. scheduling, temporal buffers, routine, autonomy, and synchronization.

The Organizational Culture Inventory (OCI, Cooke & Szumal, 1993) measures 12 sets of normative beliefs and behavioural expectations that are categorized into three general types: constructive, passive-defensive, aggressive-defensive. The Organizational Beliefs Questionnaire (OBQ, Sashkin, 1984) has ten subscales measuring organizational values: work should be fun, being the best, innovation, attention to detail, work and value of people, quality, communicating to get the job done, growth/profit/other indicators of success, hands-on management, and importance of a shared philosophy.

Concerning the alpha reliabilities of OCI, OBQ, CCS, and CGS, the OCI secondary subscales (people orientation, task orientation, satisfaction needs, and security needs) show high coefficients of internal consistency ranging from 0.89 to 0.95 (Xenikou & Furnham, 1996). This indicates that when these subscales are used, the questionnaire is the most internally reliable measure of OC compared to the other three. Using factor analysis to examine the various dimensions of OC, Xenikou and Furnham (1996) showed that a five-dimensional model of OC resulted: (1) openness to change in a supportive culture, (2) negativism/resistance to change, (3) the human factor in a bureaucratic culture, (4) positive social relations in the workplace, and (5) task oriented organizational growth. But in regard to instruments used to assess OC, it appears that within-group agreement regarding norms depends partly on the degree to which respondents are similar in terms of positional and demographic factors. Cooke and Szumal's (1993) results suggest that composite cultural profiles should be developed for subunits and groups of employees (e.g. subculture profiles) as well as for the organization as a whole.

In summary, most instruments developed in English-speaking countries and/or North-America try to assess values and vary mostly only in detail. Most of them agree on the labelling of found factors of principal component analysis. They share a common ground, in so far that almost every instrument includes factors which are labelled 'people and team orientation vs. orientation towards outcomes', and 'innovation/openness to change vs. resistance to change'.

Since the period of the middle 1980s, the perspective of culture researchers has expanded from the ideographic point of view emphasizing contextualized and ideographic aspects using field observation, to a more conventional way of comparison and generalization using methods of combined quantitative and qualitative instruments (Denison, 1996). However, measuring OC-dimensions with the help of questionnaires seems to be limited as they measure specific cultural sub-dimensions as surrogates of the cultural whole. They divide a concept which is primarily used to draw attention to the holistic aspect and prejudge the dimensions to be studied. But even if they stress cultural features that prevail across many organizations, they do not help to discover poorly understood patterns and cultural effects that are unique to a particular organization or subculture. It is not clear if the dimensions in question are relevant to a particular culture until the deeper levels of that particular culture have been determined (content validity). In addition, most researchers do not differ precisely between cultural factors, climate variables or values, normative beliefs, norms and attitudes.

Culture as a Root Metaphor

A researcher who looks at culture as a root metaphor shifts his attention to the definition of organization and what it means to be organized (Smircich, 1983). The methodology is based on common actions of employees and researchers. Insiders (employees) are 'forced' to articulate their basic assumptions, and researchers interpret verbal and non-verbal cues based on the values/norms of the insiders. The process of inquiry has to be interactive and iterative. In this regard, e.g., Argyris and Schön (1978) used a case building approach in which members of an organization wrote scenarios that revealed so called theories-in-use that guide behaviour strongly. The interpretation of the data should be done with a flexible approach in mind: the scientist remains open to the answers of his subjects for as long as possible and only then he completes his theoretical concept. This method creates mostly single case studies and makes generalization beyond a single organization almost impossible. In an extreme case, the number of theories on OC equals the number of cultures researched.

FUTURE PERSPECTIVES

As mentioned above, most instruments measuring OC as internal variable have been developed in English-speaking countries and mostly North-American organizations. To see whether these instruments prove to be valid generally and allow comparisons across organizations as promised, they should be replicated in different countries and different organizations, profit and non-profit, to prove statements of reliability and validity. Futhermore, cross-organizational comparison should be conducted to show that these instruments differentiate between organizational cultures accurately. Besides the replication of studies in which the development of instruments were presented to confirm results of reliability and factor analysis, construct validation should be a future concern. Construct validation should lead to results which show that for example 'team orientation' or 'easygoingness' is supposed to be a value and not a matter of organizational climate. In that respect the difference between values, norms, and beliefs has to be clarified on a theoretical basis in the future.

Furthermore, topics like globalization and international mergers of companies make OC an important and 'hot' topic for future discussions. The discussion of OC is also interesting in the context of workforce diversity, where multicultural teams work in multicultural companies bringing culture as internal and external variable closer together. Cultural diversity in thinking and problem solving are also relevant variables in a company. In light of the rising use of ICT (Information and Communication Technology) the research of virtual organizations will gain in importance as well. That means besides further investigations in regard to reliability and validity of existing assessment instruments, the search for relevant cultural factors should be continued.

CONCLUSIONS

It seems appropriate to think about OC in terms of cultural complexity. Reflecting the newness of the field no single methodology predominates. Choices of technique in this regard tend to be related to the researcher's long-term interest in theory building or practical application. But what is shown here is the heterogeneity of constructs to OC, that seem to exist without construct validation. The problem with traditional assessment approaches applying to OC is that they require knowledge of the relevant dimensions that are being measured. Even if they are statistically derived from large samples of items, it is not clear if the original items truly reflect critical cultural aspects. Examining particular cultural features, one needs to know the underlying context of a particular organizational culture, i.e. one would infer incorrectly from artefacts like stories, symbols, and myths if their relation to underlying assumptions were not known.

ORGANIZATIONAL STRUCTURE, ASSESSMENT OF

INTRODUCTION

The structure of organizations has long been a point of study for those interested in organizational sciences. In the 1960s and early to mid-1970s, the focus was on how the work the organization performed and the technology used to do the work was related to the structure of the organization. Other early foci included how the structure of the organization was related to so-called 'contextual' factors, including the size of the organization as well as its environment. These early investigations of organizational structure are usually placed under the rubric of contingency theory. Although these early writings on and studies of organizational structure often had the goal of being able to make generalizations about structure and its determinants across a multitude of sectors, this ambitious goal has yet to be fully realized. Much of the work that followed, including present-day studies, has been focused on particular industries or sectors of organizations. This partially stems from the increasing specialization within the field of

organizational sciences, but also is attributable to the contributions of contingency theory: the understanding that not only do the technologies used by organizations differ by such stratifications, but so do the environments in which these organizations are placed (Thompson, 1967). Although there is one set of scales that are widely referenced for their conceptualization of factors that one should consider when assessing organizational structure (Pugh, Hickson, Hinings & Turner, 1968, 1969), there are no standardized scales that are used to study all of the elements of organizational structure across all industries or sectors. What we have instead are scales that would have to be altered and applied to particular industries and psychometrically reassessed, or 'islands' of specialized research on organizational structures that are informed by the earlier work done on this topic.

The first goal of this entry is to articulate what is meant by organizational structure. This will be followed by a review of the major set of scales that has been developed to assess organizational structure, and an analysis of how researchers of one sector, health care, have assessed organizational structure.

DEFINING ORGANIZATIONAL STRUCTURE

It is important to define what is meant by organizational structure, because the definition(s) can be used to assess the face validity of any measures that a researcher could construct. Definitions of organizational structure can be classified into those that are more conceptual and those that are more operational. On the conceptual level, Mintzberg (1983) defines organizational structure as the '... sum total of the ways in which labor is divided into distinct tasks and then its coordination is achieved among these tasks' (Mintzberg, 1983: 2). The contemporary management literature defines the elements of organizational structure to include the following: formal reporting relationships and levels in the hierarchy, grouping together of individuals into departments and of departments into the total organization, and systems to include effective communication, coordination, and integration of efforts across departments (Daft, 2001: 202). Basically, conceptual definitions of organizational structure specify how the organization is differentiated in terms of tasks, reporting relationships, authority and decision-making responsibility, and how these differentiated elements are integrated to coordinate the work that the organization does.

In the operationalization and empirical study of organizational structure, the literature has gone beyond the basic conceptual notions of what constitutes organizational structure to include more specific indicators. In their classic work, Pugh et al. (1968) define the 'dimensions of organization structure' as specialization, standardization, formalization, centralization, configuration (e.g. span of control and subordinate ratios), and flexibility. In addition to his conceptual definition, Mintzberg (1981) also provides a more substantive definition of the 'elements of structure' as the specialization of tasks, formalization of procedures, formal training and indoctrination, grouping of units, unit size, planning and control systems, liaison devices, delegation of power both down and out from the chain of command (Mintzberg, 1981: 104). Daft (2000) echoes these with his structural dimensions of organizational design: formalization, specialization, standardization, hierarchy of authority, complexity in activities or subsystems, centralization, professionalism, and personnel ratios.

ASSESSING ORGANIZATIONAL STRUCTURE

There are many ways to assess the structure of an organization and many goals of such evaluations. Those who perform studies involving organizational structure have been remiss to develop and/or use a set of standardized measures that capture this concept. Instead, the research on structure is quite varied, not only in its purpose, but also in its methods, as many studies have 'reinvented the wheel' with respect to how they measure organizational structure. Like many aspects of organizational studies, there is not a lot of consensus about how to operationalize conceptual models so that they can be empirically assessed. Part of this stems from the fact that there are a great many different kinds of organizations, in many different sectors, processing many different kinds of inputs, producing

many different kinds of outputs, and with a variety of institutional and other environmental demands and constraints. Measuring the structure of organizations may not necessarily be able to be done in the same way across sectors, as the technologies used vary widely, as do the environmental conditions. Consider a large complex organization like Kraft, which has many divisions, or a large hospital that is part of a larger vertically integrated delivery system. Should or can one assess the structure of these two incredibly different organizations in the same way, using the same instruments? Certainly, this would be quite an ambitious task and was one of the goals of the Aston Group. Instead, what we have seen are measures being developed piecemeal or adapted from other work and their reliability and validity assessed on a case-by-case basis.

The scientific criteria used to assess a measure of organizational structure should be consistent with the criteria used to judge any particular measure of interest to social scientists. When assessing measures, the primary point of departure for many social scientists is face validity. Therefore, the first step in assessing whether a particular measure of organizational structure (or other organizational variables) is sound is to see if it has face validity. In the case of survey research and multidimensional scales, further steps must be taken to assess the psychometric properties of the measure using what is accepted as the standard battery of internal consistency assessments (i.e. computing Cronbach's alpha coefficients), and to assess the construct validity by ensuring that the factor analysis was performed in an appropriate way. In some cases, where the goal of the researchers may be more in-line with methodological advancements, the investigators may expend efforts to demonstrate the convergent and discriminant validity of such measures.

The classic reports by Pugh et al. (1968, 1969), the so-called 'Aston studies', measured the structure of 52 organizations in England. The Aston Group developed six conceptual measures of structure, five of which they were able to construct using their data. The six are: specialization, standardization, formalization, centralization, configuration, and flexibility, the last of which was dropped due to methodological concerns.

'Specialization is concerned with the division of labour within the organization, the distribution of official duties among a number of positions' (p. 72). For example, is responsibility for particular functions like accounting located within one position, or is it dispersed across multiple positions? Standardization of procedures is the degree to which there '... are rules or definitions that purport to cover all circumstances and that apply invariably' (p. 74). In this case, organizational procedures are conceptualized as events that have 'regularity of occurrence' and are 'legitimized by the organization'. Ideally, this would be reflective of the degree to which procedures based on customs *and* procedures based on specified bureaucratic procedures are present in the organization. 'Formalization denotes the extent to which rules, procedures, instructions, and communications are written' (p. 75). 'Centralization has to do with the locus of authority to make decisions affecting the organization' or where '...the level in the hierarchy where executive action could be authorized...' (p. 76). In other words, how far up the chain of command one has to go to get permission to take a particular action. 'Configuration is the "shape" of the role structure... [and would be indicated by] a comprehensive and detailed organizational chart' (p. 78). Often, the configuration of the organization is expressed in both the vertical and horizontal spans of control; that is, the number of levels present within the organization and the number of subordinates reporting to the managers of any particular level.

In their study of these 52 organizations, the Aston Group constructed 64 scales, some of which were subscales while others were aggregate measures of the various structural dimensions. Given that this study was done over thirty years ago, it is not surprising then that the methods used to construct and validate these scales were not the same that would be used today. The methods used by the Aston Group partially relied on a '... Brogden–Clemans coefficient to test whether the items scaled and could therefore be regarded as representing a dimension' (p. 70). The Aston researchers claimed that this was an 'index of item-total correlation' and was used because it does not assume that the data are normally distributed. The researchers then used 'principal-components analysis' to group these scales into larger factors or 'summary scales'

(p. 70). Given that this is considered a 'watershed' study for organizational researchers, it is somewhat disappointing that the authors did not provide greater detail of their methods.

Although the scales developed by the Aston Group have become the point of departure for many subsequent studies of organizational structure, some researchers have voiced concern over these scales. In fact, not long after the initial reports on the Aston scales were published, one attempt to replicate the Aston methodology was not completely successful (Child, 1972). Others claim that the variables in the Aston Group's work represent scalar and not vector measures (Mansfield, 1973). More recent research has drawn attention to additional concerns over the unidimensionality of multi-item measures and the aggregation of subscales into summary scales (Grinyer & Yasai-Ardekani, 1981).

SECTOR-SPECIFIC MEASURES

Many of the present-day studies of organizational structure have focused on large, complex organizations and the integrating mechanisms used to coordinate activity among the different parts of these organizations. In the health sector, there has been research on so-called vertically integrated delivery systems. These are multi-institutional organizations that provide a continuum of services to health care consumers, including standard inpatient care and a variety of outpatient services. How such systems and networks of component organizations are structured is important because such structures will impact the degree to which coordination can be achieved among the various components, which, in turn, is believed to have implications for the costs and quality of patient care (Conrad & Dowling, 1990). There have been three reports on the structural components of these types of organizations. One study reported on the degree of 'functional integration' of the various components of health systems, taking the per cent of affirmative responses to a series of yes/no questions pertaining to 49 potential areas that could be functionally integrated across the component organizations (Devers et al., 1994). This study did not report using psychometric techniques to assess whether all 49 potential areas of functional integration were statistically related, but appear to have relied on face validity in constructing this measure. Another study, which also examined functional integration, employed standard psychometric factor analytic techniques as well as an internal consistency analysis in the development of their measure (Gillies, Shortell, Anderson, Mitchell & Morgan, 1993). The third study's purpose was to develop a taxonomy of such health systems and networks, with the elements of the taxonomy, differentiation, integration and centralization, representing structural dimensions of these systems (Bazzoli, Shortell, Dubbs, Chan & Kralovec, 1999). These researchers did not use standard psychometric techniques to arrive at their measure of structure for these systems and network, but instead used cluster analysis and a host of confirmatory methods (split halves reliability analysis, Duncan multiple range tests, and discriminant analysis).

FUTURE PERSPECTIVES AND CONCLUSIONS

The failure of organizational researchers to develop or adopt one set of multidimensional scales to assess organizational structure arises out of the diversity of organizations present in our society. Organizational size, the work performed and the technology used to perform the work, and the organization's environment are important determinants of organizational structures. Given the diversity in organizational technologies, tasks and environments, it is not surprising that a set of standardized measures has been elusive to researchers. The one set of scales that are widely seen as covering many of the aspects of organizational structure need to be tailored to the specific industry to which they are being applied and then psychometrically reassessed. Given the lack of standardized measures, what we have seen are sector-specific measures developed for the purpose of assessing organizational structures. Organizational researchers who study the health sector have been prodigious in their development of such scales.

OUTCOME ASSESSMENT/ TREATMENT ASSESSMENT

INTRODUCTION

Outcome assessment, or treatment outcome assessment, refers to the assessment of the results of psychological treatment for a patient or group of patients on one or more dimensions of functioning. Although outcome assessment can reflect the results of psychological intervention in many settings (social, organization, school, etc.), the term is most commonly used to refer to the assessment of therapeutic interventions taking place in clinical settings.

Outcomes is one of three dimensions of quality of care identified by Donabedian (1985). The first dimension is *structure*. This refers to various aspects of the organization providing the care, including how the organization is 'organized', the physical facilities and equipment, and the number and qualifications of its professional staff. *Process* refers to the specific types of services that are provided to a patient during a specific episode of care. These might include various tests and assessments, therapeutic interventions, and discharge planning activities. *Outcomes*, on the other hand, refers to the results of the specific treatment that was rendered.

In considering the types of outcomes that might be assessed in behavioural healthcare settings, most clinicians probably would identify symptomatic change in psychological status as being the most important. However, as Sederer, Dickey, and Hermann (1996) have noted,

> Outcome for patients, families, employers, and payers is not simply confined to symptomatic change. Equally important to those affected by the care rendered is the patient's capacity to function within a family, community, or work environment or to exist independently, without undue burden to

the family and social welfare system. Also important is the patient's ability to show improvement in any concurrent medical and psychiatric disorder... Finally, not only do patients seek symptomatic improvement, but also they want to experience a subjective sense of health and well being. (p. 2)

There are numerous reasons for assessing outcomes. For example, outcome assessment can provide a direct measure of how much patient improvement has occurred as the result of a completed course of treatment intervention. Another common reason for assessing outcomes is to demonstrate the patient's need for therapeutic services beyond that which is typically covered by the patient's healthcare benefits. When assessment is conducted for this reason, the patient and the clinician both may benefit from the outcomes data.

Thus, 'outcomes' holds a different meaning for each of the different parties who have a stake in behavioural healthcare delivery, and the outcomes selected for measurement generally depend on the purpose for which the assessment is undertaken.

WHAT TO MEASURE

Probably the most frequently measured outcomes variable is that of symptomatology or psychological/mental health status. After all, disturbance or disruption in this dimension is probably the most common reason why people seek behavioural healthcare services in the first place. Thus, in the vast majority of the cases seen for behavioural healthcare services, the assessment of the patient's overall level of psychological distress or disturbance will yield the most singularly useful information.

However, measured changes in psychological distress or disturbance either (a) provide only a partial indication of the degree to which therapeutic intervention has been successful; (b) are not of interest to the patient or a third party payer; (c) are unrelated to the reason why the patient sought services in the first place; or (d) are otherwise inadequate or unacceptable as measures of improvement in the patient's condition. As alluded to earlier, one may find that for some patients, improved functioning on the job, at school, or with family or friends is much more relevant and important than symptom reduction. For other patients, improvement in their quality of life or sense of well-being is more meaningful.

It is not always a simple matter to determine exactly what should be measured. However, careful consideration of the following questions should greatly facilitate the decision:

1 Why did the patient seek services?
2 What does the patient hope to gain from treatment?
3 What are the patient's criteria for successful treatment?
4 What are the clinician's criteria for the successful completion of the current therapeutic episode?
5 What are the criteria for the successful completion of the current therapeutic episode that are held by significant third parties?

Note that the selection of the variables to be assessed may address more than one of the above issues. Ideally, this is what should happen. However, the task of gathering outcomes data should not become too burdensome. The key is to identify the point where the amount of data that can be obtained from a patient and/or collaterals, and the ease at which it can be gathered, are optimized.

Overall, the variables selected as measures of outcomes should reflect the needs and interests of the patient, clinician, and relevant third parties.

HOW TO MEASURE

Once the decision of *what* to measure has been made, one must then decide *how* it should be measured. In many cases, the most important data will be that obtained directly from the patient using self-report instruments. Underlying this assertion is the assumption that (a) valid and reliable instrumentation, appropriate to the needs of the patient, is available to the clinician; (b) the patient can read at the level required by the instruments; and (c) the patient is motivated to respond honestly to the questions asked. Barring one or more of these conditions, other options should be considered. Rating scales completed by the clinician or other members of the treatment staff may provide information that is as useful as that elicited directly from the patient. Examples include parent-completed inventories for child and adolescent patients. Collateral rating instruments

can also be used to gather information *in addition to* that obtained from self-report measures. When used in this manner, these instruments provide a mechanism by which the clinician, other treatment staff, and/or parents, guardians or other collaterals can contribute data to the outcome assessment endeavour.

Another potential source of outcomes information is administrative data. In most large provider organizations, this information can easily be retrieved through the organization's management information systems. Data related to the patient's diagnosis, dose and regimen of medication, physical findings, course of treatment, resource utilization, and treatment costs, along with other types of data typically stored in these systems, can be useful in evaluating the outcomes of therapeutic intervention.

In summary, outcomes information can be obtained from many different sources that can reflect different perspectives of the results of psychological treatment.

WHEN TO MEASURE

There are no hard and fast rules or widely accepted conventions related to when outcomes should be assessed. The common practice is to assess the patient at least at treatment initiation to obtain a baseline measure, and then again at termination/discharge. Additional assessment of the patient can take place at other points in time; that is, at other times during treatment and/or upon post-discharge follow-up.

Many would argue that post-treatment follow-up assessment provides a good indication of the enduring effects of treatment, and thus is the best or most important indication of the outcomes of a therapeutic intervention. Two types of comparisons may be made on follow-up. The first is a comparison of the patient's status, either at the time of treatment initiation or at the time of discharge or termination, to that of the patient at the time of follow-up assessment. The second type of post-treatment investigation involves comparing the frequency or severity of some aspects of the patient's life circumstances, behaviour or functioning which occurred during an interval of time prior to treatment, to that which occurred during an equivalent period of time immediately preceding the post-discharge assessment. A good example is a comparison of the utilization of medical and/or behavioural health services during the three months prior to treatment to that which occurred during the three months following treatment termination. This approach is commonly used in determining the medical cost-offset benefits of treatment.

In general, post-discharge outcome assessment probably should take place no sooner than one month after treatment has ended. Waiting three to six months to reassess the patient can provide a good indication of the lasting effects of treatment and therefore is preferred. Assessments being conducted to determine the frequency at which some behaviour or event occurs (as may be needed to determine cost-offset benefits) should be administered no sooner than the reference time interval used for the baseline assessment.

Thus, comparison of outcome measures obtained a few months after treatment termination to those obtained at the beginning of treatment can provide a powerful demonstration of the benefits of treatment.

HOW TO ANALYSE OUTCOMES DATA

There are two general approaches to the analysis of treatment outcomes data. The first is by determining whether changes in patient scores on outcome measures are *statistically significant*. The other is by establishing whether these changes are *clinically significant*. Use of standard tests of statistical significance is important in the analysis of group or population change data. Clinical significance is more relevant when evaluating change on measures for individual patients.

The issue of clinical significance has received a great deal of attention in psychotherapy research during the past several years. This is at least partially owing to the work of Jacobson and his colleagues (Jacobson & Truax, 1991; Jacobson, Follette & Revenstorf, 1984, 1986). Their work came at a time when researchers began to recognize that traditional statistical comparisons do not reveal a great deal about the efficacy of therapy. In discussing the topic, Jacobson and Truax broadly define the clinical significance of treatment as 'its ability to meet standards of efficacy set by consumers, clinicians, and researchers' (p. 12).

Jacobson and his colleagues view the determination, clinically significant change as being a

function of both the changes in the outcomes variables from pre- to post-treatment and the patient's functional status at the end of therapy. To this end, Jacobson et al. (1984) proposed the use of a reliable change index (RCI) to determine whether change is statistically significant. This index, modified on the recommendation of Christensen and Mendoza (1986), represents the pre-test score minus the post-test score divided by the standard error of the difference of the two scores. At the same time, Jacobson et al. felt that change in functioning could be conceptualized in one of three ways. Thus, for clinically significant change to have occurred, the RCI must be significant at at least the 0.05 level *and* the measured level of functioning must change such that following the therapeutic episode, it must either (a) fall outside the range of the dysfunctional population by at least two standard deviations from the mean of that population, in the direction of functionality; (b) fall within two standard deviations of the mean for the normal or functional population; or (c) be closer to the mean of the functional population than to that of the dysfunctional population. Jacobson and Truax viewed the third option (c) as being the least arbitrary, and they provided different recommendations for determining cutoffs for clinically significant change, depending upon the availability of normative data.

Overall, the assessment of clinically significant change is relatively easy and provides information that is more useful than that allowed by statistical significance testing alone.

BENEFITS OF OUTCOME ASSESSMENT

Cagney and Woods (1994) identified several benefits that can accrue from assessing outcomes. For patients, these include enhanced health and quality of life, improved healthcare quality, and effective use of the money paid into benefits plans. For providers, the outcomes data can result in improved clinical skills, information related to the quality of the care provided and to local practice standards, increased profitability, and decreased concerns over possible litigation. Outside of the clinical context, benefits also can accrue to payers and managed care organizations (MCOs). Potential payer benefits include healthier workers, improved healthcare quality, increased worker productivity, and reduced or contained healthcare costs. As for MCOs, the benefits include increased profits, information that can shape the practice patterns of their providers, and a decision-making process based on delivering quality care. In sum, outcome assessment can yield benefits to all of those who have a stake in treatment of any given patient.

FUTURE PERSPECTIVES

As the realization of the importance of outcome assessment continues to grow, so too will its implementation by the behavioural healthcare providers and organizations. The advances in technology that occurred during the last decade and those that will undoubtedly occur during the coming decade will facilitate this. In particular, the Internet will enable the cost-effective and efficient administration, scoring, analysis, and reporting of outcomes data, making it a key component in outcomes systems. Also, analysis of outcomes data will become more sophisticated and allow more useful information (e.g. for treatment matching, prediction of level of improvement) to be obtained. In all, outcome assessment will become an integral part of the behavioural healthcare delivery system and will ultimately result in greater patient improvement and satisfaction with treatment services.

CONCLUSIONS

In an era where the value of traditional psychological assessment is being questioned, outcome assessment is quickly gaining acceptance and becoming one of the most commonly performed types of assessment in the behavioural healthcare field. Many psychologists are uniquely qualified by their training to develop and oversee outcome assessment programmes. Consequently, those with the appropriate clinical and research training and experience are in an excellent position to both advance their value as a service provider and to significantly contribute to the advancement of the profession in the healthcare field.

OUTCOME EVALUATION IN NEUROPSYCHOLOGICAL REHABILITATION

INTRODUCTION

The evaluation of functional outcome of individuals with acquired brain injury (ABI) after discharge has become an integral part of rehabilitation programmes. It is the best way to corroborate the effectiveness of the treatment and to justify charges for rehabilitation services (Cope & O'Lear, 1993; Hall et al., 1994). The quality of a rehabilitation centre is related to the objectively measured outcome obtained upon conclusion of the patient's rehabilitation period.

Outcome is influenced by different factors and is not obtained by measuring any single concept. Acute factors determining the process of acute and post-acute rehabilitation are: the Glasgow Coma Scale (GCS) score on hospital admission, length of coma (LOC), duration of post-traumatic amnesia (PTA), family support, and social status.

In this entry we review the most important and widely used instruments for measuring outcome after acquired brain injury: the Glasgow Outcome Scale (GOS), the Disability Rating Scale (DRS), the Functional Independence Measure (FIM), the Functional Assessment Measure (FAM), Rancho Los Amigos Level of Cognitive Functioning Scale (LCFS), Community Integration Questionnaire (CIQ), the Neurologically-related Changes of Emotions and Personality Inventory (NECHAPI), and the Portland Adaptability Inventory (PAI).

THE GLASGOW COMA SCALE (GCS)

The Glasgow Coma Scale is one of the oldest scales used for measuring outcome after brain injury and was widely used before the development and implementation of new scales. The GCS was developed by Jennett and Bond in 1975 and an extended version by Wilson, Pettigrew and Teasdale appeared in 1998. The original scale has five categories or levels and is very easy

to apply. It does, however, have very poor sensitivity. Upon discharge from an acute care unit or from hospital, the patient is included in one of the 5 levels of the GOS: level 1 is death, level 2 is persistent vegetative state (absence of cortical function), level 3 is severe disability (conscious but disabled), level 4 is moderate disability (disabled but independent), and level 5 is good recovery (back to normal life). These levels can also be grouped as poor outcome (GOS 1–3) and good outcome (GOS 4–5). The extended version divides each of the last 3 levels into 2 each, with a total of 8 levels.

THE DISABILITY RATING SCALE (DRS)

The Disability Rating Scale was developed by Scranton, Fogel and Erdman in 1970 as a measure of general functional status. The usefulness of the DRS in measuring outcome of people with traumatic brain injury was tried by Rappaport, Hall and Hopkins in 1982 in an attempt to improve the GOS. It is easy to administer and an important advantage is that scoring can be used from the acute phase (baseline) up to the discharge of the patient, covering the different recovery phases. The DRS consists of eight categories (the first three categories are simple modifications of the Glasgow Coma Scale) which can be scored from direct observation of the patient, from a personal interview with the patient and even from a phone interview. The DRS has good validity and is highly reliable (Eliason & Topp, 1984; Gouvier et al., 1987; Fleming et al., 1994). On the downside, the DRS has poor sensitivity when used with people with mild traumatic brain injury (DRS < 3) or with people with severe disability (DRS > 22). To increase sensitivity, Hall, Mann, High, Wright, Kreutzer and Wood (1996) recommend adding a half-unit to items 4 to 8. This scale seems to have less ceiling effects than FIM or FIM+FAM.

THE FUNCTIONAL INDEPENDENCE MEASURE (FIM)

The Functional Independence Measure was developed by Keith, Granger, Hamilton and Sherwin in 1987 as a 7 point rating scale with 18 items (a score of 1 for complete dependence and 7 for complete independence). The FIM evaluates self-care (eating, washing oneself, showering/bathing, getting dressed, going to the toilet), sphincter control (vesical and anal sphincter), mobility (movement from the bed, chair and wheelchair, toilet, bath or shower), communication (comprehension, expression), psychosocial adjustment (social interaction, employability), and cognitive function (problem solving and memory). It is one of the most widely used tools to evaluate the functional status of neurological patients, and has been extensively used with patients with traumatic brain injury. Inter-rater reliability is between 0.86–0.97 (Hamilton et al., 1991; Linacre et al., 1994) and it seems to show a good face validity, internal consistency and discriminative capability (Dodds et al., 1993).

The FIM mainly measures common motor and self-care tasks found in everyday activities (13 items, with a maximum possible score of 91). The cognitive deficits (5 items, with a maximum possible score of 35) of the subjects are infra-represented. The principal problem found in this scale is the ceiling effect.

THE FUNCTIONAL ASSESSMENT MEASURE (FAM), THE FIM+FAM

The FAM was created to give more consistency to the FIM and thus eliminate the 'ceiling effect' detected in the latter. The FAM contributed 12 new items which evaluate cognitive, behavioural, communication and psychosocial information. Given that the cognitive or emotional items which are added by the FAM are more complex and difficult to evaluate (unless the person carrying out the observation is trained) through simple observations, the inter-raters reliability has not been well established. The additional items are related to orientation, attention and emotions. The validity correlates significantly with clinical data of the acute phase, as well as with the length of coma, post-traumatic amnesia and Glasgow Coma Scale scores (Hall et al., 1993). León-Carrión (2002) has recently developed a new formula for the FIM+FAM, offering three new functional indexes: Maximum Recovery Percentage, Index of Functionality at Admission

and Index of Functionality at Discharge. The indexes can be applied to the complete scale and to each of the 5 categories of the scale.

RANCHO LOS AMIGOS LEVEL OF COGNITIVE FUNCTIONING SCALE (LCFS)

This scale was originally designed (Hagen et al., 1972) as a useful and easy tool to classify the cognitive functioning of patients with traumatic brain injury. It is widely used in the acute phase, and also currently as an outcome measure after the patient has been discharged. There are 8 levels to which a patient may be assigned on the LCFS: I. no response, II. generalized response, III. localized response, IV. confused/agitated, V. confused/inappropriate, VI. confused/appropriate, VII. automatic/appropriate and VIII. purposeful/appropriate.

Table 1 gives a more detailed description of each level.

COMMUNITY INTEGRATION QUESTIONNAIRE (CIQ)

The CIQ (Willer et al., 1993) has been designed specifically to evaluate the success of the return to the community of a patient with acquired brain injury. It is a 15-item questionnaire evaluating home integration, social integration and integration into productive activities. Questions refer to everyday independent activities such as shopping, household activities, food preparation, visiting friends and so forth. Items are scored from 0 to 2 obtaining a total single score of community integration. The higher the score the better the social integration.

NEUROLOGICALLY RELATED CHANGES OF EMOTIONS AND PERSONALITY INVENTORY (NECHAPI)

The NECHAPI (León-Carrión, 1998) is a clinical tool specifically designed for observing emotional changes presented by individuals who have sustained traumatic brain injury, or with cerebrovascular disorders, brain tumours and neurological disorders. It contains 40 items which family members must rank from 1 to 5, depending on how they feel it defines the patient, a score of 5 being indicative of a high occurrence rate and a score of 1 indicating minimum frequency. Intermediate scores also exist. Family members score each item twice, the first time with reference to the patient before the neurological disorder and the second time with reference to the patient's present neurological status. The 40 items of this inventory are grouped into five factors: anger, sensation seeking, emotional vulnerability, sociability and emotional coldness. The reliability is 0.85. The NECHAPI can be repeated at any time to monitor the emotional progress of the patient after neurorehabilitation,

Table 1. Rancho Los Amigos scale of cognitive functioning

Level I. *No response to pain, touch, or sight*
Level II. *Generalized reflex response to pain*
Level III. *Localized response* Blinks to strong light, turns toward/away from sound, responds to physical discomfort, inconsistent response to commands.
Level IV. *Confused/Agitated* Alert, very active, aggressive or bizarre behaviour, performs motor activities but behaviour is non-purposeful, extremely short attention span.
Level V. *Confused/Non-agitated* Gross attention to environment, highly distractible, requires continual redirection, difficulty learning new tasks, agitated by too much stimulation. May engage in social conversation but with inappropriate verbalizations.
Level VI. *Confused/Appropriate* Inconsistent orientation to time and place, retention span/recent memory impaired, begins to recall past, consistently follows simple directions, goal directed behaviour with assistance.
Level VII. *Automatic/Appropriate* Performs daily routine in highly familiar environment in a non-confused but automatic robot-like manner. Skills noticeably deteriorate in unfamiliar environments. Lacks realistic planning for own future.
Level VIII. *Purposeful/Appropriate* Independent and capable of processing new information. Distant and recent events can be remembered and can figure out complex and simple problems.

as well as to monitor the effect of neuropharmacotherapy on the emotional life of individuals with neurological disorders.

PORTLAND ADAPTABILITY INVENTORY (PAI)

The Portland Adaptability Inventory was created by Muriel D. Lezak in 1987 (see Lezak, 1995) to systematically evaluate the personality and social maladjustment that people with traumatic brain injury can exhibit. Items, with the exception of the alcohol and drugs items, are rated from 0 to 3. Rating is based on raters' observations, family reports, medical records, clinical observations and social history. The internal consistency coefficient is 0.938 for the total inventory. Items are grouped into 3 different scales: Temperament and Emotionality (T/E), Activities and Social Behaviour (ASB) and Physical Capabilities (PC). Some authors found the PAI useful in predicting, at admission, the vocational possibilities of patients following treatment, especially of patients with minor or moderate brain injury (Malec et al., 1991).

FUTURE PERSPECTIVES AND CONCLUSIONS

Outcome measurement after acquired brain injury rehabilitation will be an essential and indispensable task for neuropsychologists working in this field. The goal of outcome measurement is to evaluate the benefit of rehabilitation. Objectification of the results of rehabilitation will become increasingly prevalent due to the demands of insurance companies and patients' families. The other great challenge for neuropsychologists working in this area will be to correlate functional outcome measures to the neuroimages of the patients taken prior to and after neuropsychological rehabilitation (León-Carrión, 1997).

PALLIATIVE CARE

INTRODUCTION

The Palliative Care Movement is based mainly on the modern Hospice Philosophy concerning end-of-life care, its main exponent being the St. Christopher Hospice, founded by C. Saunders. She explains (Sanders, 1993) the two key points that form the nucleus of this philosophy:

- 'the message is: you matter because you are you, and you matter until the last moment of your life. We will do all we can, not only to help you die peacefully, but also to live until you die.'
- the concept of Total Pain (including physical, psychological, social and spiritual elements).

The author also lists the elements that St. Christopher's brought together to set up this work: (a) beds integrated in local community; (b) development and monitoring of symptom control; (c) family support; (d) bereavement service; (e) home care; (f) research and evaluation; and (g) education and training.

There are also some key events that have promoted the expansion and consolidation of this care system:

- The work by Kübler-Ross, using a large series of interviews with terminal patients talking about dying, and reflected in her famous book *On Death and Dying*. This had a huge impact on the public and on many health professionals in the 1960s.
- The beginning of the movement in the USA, in 1974, headed by S. Lack, and its subsequent impact of home care in this country; not long thereafter the same resources were adopted in the UK.
- The first use of the term 'palliative care', as a non-stigmatizing one, by B. Mount, who opened the Palliative Care Service at the Royal Victoria Hospital in Montreal, and its subsequent introduction in other countries.
- In 1987, Palliative Medicine was recognized as a medical speciality in the UK.
- In 1990, the WHO stated that the correct term for this system of care is 'Palliative Care', offering a useful definition thereto: 'The active total care of patients whose disease is not responsive to curative treatment, control of pain, of other symptoms, and of psychological, social and spiritual problems, is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families. Many aspects of palliative care are also applicable early in the course of the illness in conjunction with anticancer treatment.'

And as Doyle et al. (1993) have emphasized, WHO adds: 'Palliative care ... affirms life and regards dying as a normal process ... neither hastens nor postpones death ... provides relief from pain and other distressing symptoms ... integrates the psychological and the spiritual aspects

of care ... offers a support system to help patients live as actively as possible until death ... offers a support system to help the family cope during the patient's illness and in their own bereavement.' As we can see, this implies:

- continuity of care
- multidisciplinary, global care
- family care.

Palliative care researchers and clinicians point out that the main aim of palliative care is to provide as much comfort and/or well-being as possible for patients and families. This, however, is not a simple task, and if we delve deep enough, we can detect many questions that are difficult to answer; in this entry, I will try to point out some considerations about them, justifying the need for assessment, and the areas that we must take in to account to do so appropriately.

The reasons for assessment are ethical, professional and socio-political. First of all, we need to know if we are really promoting well-being, and alleviating suffering, from the points of view of patients and families, as well as what type of interventions produce the effects. Second, we must take cognizance of the real needs of patients so as to learn about such needs, and also to train health professionals and students (instructing them in the right therapeutic instruments). And lastly, nowadays the consolidation of palliative care will not receive support, at least until it can be evaluated, demonstrating a positive cost-efficiency balance (Bayés, 2000).

Some phenomena that complicate the issue of assessment in this field are as follows:

- Different conditions or pathologies in patients
- The changing nature of the terminal situation
- The multiple factors incurred therein
- Differing ages of patients
- The necessary multidisciplinary and interdisciplinary approach/es
- The double objective: patient and family.

DEFINITION OF MAIN ASSESSMENT OBJECTIVES

If clinical global targets are to alleviate suffering and promote well-being, we must assess both phenomena in a comprehensive and systematic way.

Regarding *well-being*: this term has been assimilated to that of *quality of life*; nevertheless, it is possible that instruments of quality of life used in other domains of health will be useless in this case, because they include some certain components that are probably irrelevant to this situation (e.g. functional status will always deteriorate). Researchers try to seek the most suitable measures; they also are constructing new supplementary scales for the usual instruments (Sprangers et al., 1998). Other authors propose that a single question, posed on a linear or categorical scale, should be used to assess quality of life, in preference to other available methods (Donnelly & Walsh, 1966).

On the other hand, the term *suffering* has been assessed in many ways: i.e. psychological suffering (anxiety and depression); presence of physical symptoms, pain as the most devastating symptom; the expressed needs of patients; and, recently, spiritual aspects. All of the above are necessary to understand the situation of patients and family, but it will also be necessary to have global measures of suffering in addition to the specific aspects that contribute to it.

Further, we must seek adequate measures, verbal and/or non-verbal, but always be able to evaluate the subjective perception of the individual about suffering. As we have shown in our research work, the presence of a symptom, and the worry about it, does not always correlate (Barreto et al., 1996). We have made some proposals regarding the global assessment of suffering and well-being (Bayés et al., 1995) using as an indirect reference the fact of how quickly, or how slowly, time passes.

I believe that it is also very important to have *conceptual models of reference* which underlie assessment. Hence, each researcher will have the same framework to advance in knowledge. In this sense, we understand suffering in a way similar to Chapman and Gravin (1993), who did so on the basis of the Lazarus and Folkman notion of threat; the degree of suffering being the result of balance between perceived threat and resourcefulness.

It is also important to emphasize that we need to assess a dynamic adaptation process, not an act, due to the proximity of death and the changing nature of illness progression. In sum, the assessment must be brief, non-intrusive,

global and specific, including sensitivity to rapid changes.

Finally, it is especially relevant to measure *outcomes in palliative care*. Issues included are the utilization of appropriate measurements, study populations, outcomes, accountability, standards of hospice care, etc. Moreover, a research effort is required to develop measurement tools which will utilize patient and family perspectives to measure quality of care (Teno, 1999), taking into account that nearer the death, life takes on new shape, values change and things once ignored become more important. Existing quality-of-care measures do not attend to changes in priorities or to dimensions that acquire new significance. Likewise, it is very important to evaluate palliative care services and identify gaps in them. The identification of unmet needs will be crucial to the development of services which enable people to die in a well-supported environment.

An important review of literature on quality of care, in palliative care settings, was carried out by Hearn and Higginson in 1998. The main objective was to determine whether teams providing specialist palliative care improve health outcomes of patients with advanced cancer, and their families or carers, when compared to conventional services. Improved outcomes were seen in the amount of time spent at home by patients, satisfaction of both patients and their careers, symptom control, a reduction in the number of inpatient hospital days, a reduction in overall cost, and the patients' likelihood of dying where they wished, for those receiving specialist care from a multiprofessional palliative care team. When compared to conventional care, there is evidence that specialist teams in palliative help improve satisfaction, and identify and deal with more patients and family needs. Moreover, palliative care reduces the overall costs by reducing the amount of time patients spend in acute hospital settings. Further evidence can be found in another study by Axelson and Christensen (1998) on financial assessment.

The most frequently used instruments in palliative care settings have been quality of life instruments, such as the MacGill Quality of Life Questionnaire (MQOL) (Pratheepawanit et al., 1999); or a supplementary scale of the QLQ-C30 by The EORTC Quality of Life Study Group (Sprangers et al., 1998). Also, the Edmonton Symptom Assessment System (ESAS) (Bruera et al., 1991), and the Support Team Assessment Schedule (STAS) as an audit instrument (Carson et al., 2000). Moreover, the Hospital Anxiety and Depression Scale (Zigmond & Snaith, 1983) has been used to assess psychological states, as well as different instruments to assess pain.

FUTURE PERSPECTIVES

Many more studies need to be developed to know the real impact of the palliative care movement. Global assessment of suffering and well-being should be carried out with brief, simple, sensible, non-intrusive and useful instruments. We must, too, improve services, making effective evaluations of present gaps and unmet needs of patients and families, from the points of view of users. Indeed, efficiency must be demonstrated, avoiding methodological problems of studies already made. I wish to stress the need for more assessment in some abandoned areas. For instance, family needs and well-being, both in illness, and thereafter in bereavement situations. Far more assessment is needed in the field of gerontology and other non-oncologic pathologies. Demented patients and children deserve special attention.

CONCLUSIONS

Palliative Care is a relatively new field dealing with the dignity of dying people and their carers; to date, research has shown its usefulness, to some extent, for patients, families and multidisciplinary health teams. Various trials have been made to assess a number of aspects of this type of care, and the global results thereof. Partial assessment of quality of life, symptoms, specific pain, spirituality and quality of care is now being undertaken. We need global measures to complement this. We also need to know how efficient palliative care is, together with contributions of different professionals.

PERCEIVED ENVIRONMENTAL QUALITY

INTRODUCTION

In the last three decades, research in the field of Environmental Psychology has undertaken the task of developing applications for resolving community problems. This is not a specific characteristic of Environmental Psychology, but it has nevertheless served as one of its evolutionary foundations. As Stokols (1995) pointed out, in recent years, applications of environmental-behaviour studies have been oriented towards the solution of certain socio-environmental problems. These include those related to life in the city (stress, noise, overcrowding), residential environment (both indoor and outdoor), working environment, natural resources management (energy, water, air, etc.), natural environments (landscape, preserved and recreational areas, etc.), institutional buildings (housing, schools, etc.), and so on. This has allowed applications in the field of environmental and behavioural research to gain strength in the improvement of public policies and social problem-solving. Researchers believe that their work will eventually help to ameliorate

these problems, maintaining the concept of environmental quality both explicitly and implicitly present at all times. It is necessary to obtain better measures of environmental quality to aid the development of better recommendations for the improvement of human settings.

The term environmental quality has a range of meanings. In a general sense, it refers to the properties or features of a physical environment that define it as an optimal resource in itself or in comparison to others, taking into account present or future human well-being. In psychological terms, environmental quality can be defined as the properties or attributes of a given socio-physical environment that positively influence a person's state of health, a community's well-being and people's capacity to achieve the goals that guide their behaviour. Environmental quality can be considered a synonym of environmental stimulation quality, including both social and physical traits (Wohlwill, 1976). It can alter a person's emotional state, cognitive competence or level of behavioural performance (Evans, 1999), and can influence health and behaviour either positively or negatively, depending largely on whether the quality is 'high' or 'low'.

ENVIRONMENTAL ASSESSMENT FRAMEWORK

The concept of environmental quality and, especially, the concept of perceived environmental quality have been used in the environmental assessment framework. Environmental assessment has been defined as a set of standard procedures for examining and measuring the physical, social and institutional properties of environmental settings (Craik, 1971; Zube, 1980, 1991). Therefore, these procedures describe the relationship between human behaviour and environmental quality in terms of physical, behavioural, descriptive and evaluative measures.

Research on perceived environmental quality and related issues is based on four basic concepts of indisputable importance. The first of these concepts is that of environmental dispositions (Craik & Zube, 1976), which refers to people's tendencies in responding to urban, rural or other types of environments. The second basic concept is that of Social Climate (Moos & Lemke, 1992, 1996). This concept provides the theoretical basis evaluating the psychological impact of residential or institutional settings. Behaviour setting (Barker, 1968), a traditional term within ecological psychology, is the third concept, and refers to the relationship between behaviour and a specific space (*learning about a specific behaviour*, *examining it in its natural environment*, etc.). Environmental competence (Lawton, 1982), based on studies with groups of elderly people, is the fourth concept. It deals with people's satisfaction and achievement of goals in their interaction with environmental resources.

However, a lack of conceptual integration and an absence of relationships among empirical findings measured with theoretical concepts also characterize this field. Various perspectives have acknowledged the need for theoretical integration and the development of conceptual models for environmental research (Gärling, 1998; Stokols, 1995; Canter & Kenny, 1982).

The assessment of perceived environmental quality is a broad notion covering a variety of approaches. In consequence, several different kinds of environmental assessment have developed, depending on the following four criteria:

(a) Type of setting or environment. The assessment of environmental quality may refer to a physical molar environment (large-scale environment) or to a particular environmental aspect (small-scale environment), such as air pollution, water, noise, and so on.
(b) Type of environmental quality indicators. In this sense, Craik (1983) makes a distinction between technical environmental assessment (focused on the recording of the objective physical qualities of a setting and the appraisal of those qualities) and observational environmental assessment (based on the consensual impressions of the places being assessed, in an ordinary language framework, provided by panels of observers).
(c) Type of subjective judgement requested of people, as defined by Kaplan (1991). In this sense, assessment of an environment or setting may be based either on preferential judgement or on a comparative appraisal of different places (Craik & McKechnie, 1974).

(d) Relationship between environmental quality assessment and the decision-making process. In this respect, a distinction is made between predictive (or previous) environmental quality assessment and post-environmental quality assessment. Post-Occupancy Evaluation (POE) is a relevant case of the latter.

Environmental quality assessment is aimed mainly at clarifying environmental policy goals, appraising the effectiveness of environmental protection programmes, estimating the environmental impact of private and public projects and to establish connections between experts' approaches and the needs of lay people (Craik, 1983). Environmental quality criteria are normally based on physical parameters. These parameters are themselves based on specific technical knowledge held by experts, rather than on the subjective appraisal of the place by users or other lay people. Nevertheless, a comprehensive assessment of environmental quality must include both the quality assessment of an environment and its properties and indices of how the environment is perceived.

PERCEIVED ENVIRONMENTAL QUALITY INDEX (PEQI)

The term perceived environmental quality is used, in this context, to denote the environmental quality assessment of a given place from a user's or resident's own experience. Psychologists and experts from other fields (architects, planners, engineers, etc.) have stressed the need for these kinds of studies. As early as 1975, in reference to the land-use quality problem, the National Academy of Sciences and the National Academy of Engineering recognized that 'taking people's measurement of perceived environmental quality into account is an approach which can improve our understanding of land-use, as well as that of many other environmental problems' (NAS-NAE, 1975: 42, cited by Craik, 1983).

Craik (1983) defines Perceived Environmental Quality Index (PEQI) as 'a measure of the quality of a place or setting derived from individuals' evaluations. The index takes account of people's perception of the pertinent attributes of a place and also weights them according to their perception of relative importance' (Craik, 1983: 70).

According to Craik, Perceived Environmental Quality Index can be used for:

(a) Assessing environmental quality aspects involved in the transactions between people and the environment, such as noise pollution, overcrowding, climate, scenic quality of a place, etc. From this point of view, perceived environmental quality is defined as quality of stimulation for individual performance. The main question concerns the extent to which an individual experience of a place or setting aids or constrains the achievement of the individual's goals.

(b) Adding new criteria to technical quality assessment from users' or observers' point of view. This is the case, for example, of studies on the scenic quality of natural landscapes, which are considered to have a high scenic quality due to their ecological or biological importance. Some perceptual variables, such as the presence or absence of vegetation or water, or level of physical deterioration, have been added as new criteria (Daniel & Vinning, 1983).

(c) Estimating the congruence between perceived environmental quality and the objective conditions that favour public health (e.g. in relation to air or noise pollution). An open question in this area is how to relate the assessment of the environmental objective conditions to perceived environmental quality.

(d) Enabling a person-centred as well as a place-centred environmental quality assessment.

For many years, the concept of perceived environmental quality has been employed more in the solution of a variety of environmental problems than as a specific paradigm or approach. During the 1970s and 80s, a series of studies focused on different settings or places with the object of formulating perceived environmental quality indices. An overview of these research developments is presented by Craik and Feimer (1987: 893), and is summarized in Table 1, following the distinction, previously referred to, between technical assessment procedures and the observational assessment approach (the most important references in these scales are also included in the above mentioned chapter by Craik and Feimer).

METHODOLOGICAL ISSUES

The Perceived Environmental Quality Index was considered by Craik and Zube (1976) as a standardized procedure to include users' appraisals in the formulation and assessment of public policies and private projects.

As technical devices for evaluative research, perceived environmental quality indices are a predominant feature of self-report techniques. Participants are requested to give an appraisal of the quality of a particular setting or an aspect of it. Although the majority of research on perceived environmental quality is based on people's direct appraisals, it has recently become important to use groups of trained observers to register the relevant actions and situations in the assessment of an environment's quality. Evans (1999) considers the use of trained observers helpful in determining an environmental factor's behavioural, cognitive and emotional effects. This permits the study not only of personally perceived environmental dimensions, but also of the imperceptible dimensions a lay person (non-expert) senses as environmental stimulation, but which he or she is incapable of determining as caused by a particular environmental parameter.

Hence, perceived environmental quality assessment aims to establish a procedure for participants to give their descriptive appraisal of a physical environment. A standard, valid, reliable and widespread device, enabling the integration of results and accumulation of knowledge on perceived environmental quality assessment, is difficult to attain due to several methodological problems. These problems result from: (1) different samples of environments, (2) different kinds of environmental descriptive assessments and the variety of judgements, (3) the different ways in which environmental stimuli are presented and (4) the diversity of environmental attributes considered.

With regard to the problem of different samples of environments, perceived environmental quality assessment has been used with a wide diversity of places, settings and environmental characteristics. The range of environments whose perceived quality has been appraised includes: visual quality of a landscape, indoor features of a dwelling, and assessment of neighbourhoods, public spaces (squares, streets, etc.), building façades, work settings, educational settings, institutional spaces for children and elderly people, and so on. This has recently led Lawton (1999) to employ the label 'environmental mosaic'. A certain conceptualization is required in the face of such a diversity of environments. Lawton, following Bronfenbrenner's (1979) well-known conceptualization, proposes an environmental taxonomy that makes a distinction between physical environment, personal environment, small group environment, suprapersonal environment and macro-social environment. In spite of the relevance of his contribution, further effort is required to make each one of these types of environment operational, as well as to accurately differentiate between them in order to accumulate further knowledge on perceived environmental quality assessment.

The second problem refers to the different descriptions and subjective judgements researchers have requested from participants, as pointed out by Craik and Feimer (1987). Two kinds of indices can be specifically identified: indices based on preferential judgement and indices based on comparative subjective judgements. The first type expresses an individual's appraisals of the quality of an environment. The second type is used to register an individual's quality assessment of an

actual physical environment in comparison to a given criterion or in comparison to a place with which he or she is familiar. An example from a classic study in this field illustrates the relevance of this differentiation. In their research on neighbourhood assessment, Carp and Carp (1982: 281) include a general preferential judgement item: *living in a local area makes respondent feel angry or peaceful*. It also includes subjective judgements in comparison to a general criterion (*satisfaction with local area as a place to live*) or in comparison to other places (*feelings about block: one of the worst in this part of town or one of the best in this part of town; or rating of local area compared to the ideal*). Craik and Zube (1976), since the very first studies on PEQIs, recognized the fact that indices based on preferential judgements are more closely related to the observer's particular characteristics than indices based on comparative judgements. The latter reveals the existence of greater consensus between observers, as well as among experts and non-experts.

Thirdly, variations may be due to the different ways in which an environment is presented. Since the first studies on perceived environmental quality assessment, there have been technical innovations in the presentation of environmental features. Given their historical significance, mention should be made of research with an environmental simulator at the University of Berkeley, as well as previous studies carried out at the University of Surrey using scale models for the assessment of room cosiness. Furthermore, several studies on perceived environmental quality assessment have taken place in settings that were the object of assessment (residential and institutional locations, schools or workplaces). Different perceived environmental quality assessment strategies can be identified: appraisal of the actual place or setting considered, or simulated presentation, using photographs, pictures, audiovisual images and computer simulations. Recent research has proposed the assessment of concepts of a setting that people have in mind, or of generic places (Kramer, 1995).

The fourth and last problem, of special importance, refers to the diversity of results, given the wide variety of attributes considered in environmental quality assessment strategies. Attributes are features that can be used to subjectively describe an environment, and thus differentiate it from others. To quote Lawton (1999) 'the number of attributes is large and open ended'. In 1987, after reviewing more than thirty studies on perceived environmental quality assessment, Corraliza proposed the classification of attributes in three categories: (1) physical quality descriptors of a place (e.g. size, illumination or ventilation), (2) attributes that depict the salient features of a place or setting (e.g. the predominance of natural versus constructed elements of a scene), hence explaining subjective judgement, and (3) the emotional dimensions that characterize the observer's environmental experience (e.g. affective qualities, according to the terminology of Russell, Ward & Pratt, 1981). Lawton, in the above-mentioned contribution, acknowledges the need to differentiate between descriptive attributes and evaluative attributes of an environment or setting. Descriptive attributes are likely to affect a person's behaviour, but do not necessarily enable him or her to make a positive or negative judgement about the setting (for instance, its size or scale, or its novelty or familiarity). On the other hand, evaluative attributes are defined by subjective judgements that can be represented as variables on a continuum from positive to negative. Table 2 shows a list of attributes based on that of Lawton (1999).

FUTURE PERSPECTIVES AND CONCLUSIONS

As outlined above, much of the research on perceived environmental quality has involved the assessment of specific places with highly variable scales. Rapid changes in communication and information technologies, increasing concern over global environmental problems, and other more or less dramatic aspects (such as loss of scenic quality of urban and natural landscapes or increasing vulnerability to environmental risks, among many others) are reflecting the need to study new factors that affect the quality of the environment but are ignored in people's direct and immediate perceptive appraisals. The influence of emerging illnesses (AIDS, certain types of food poisoning, etc.), technological risks, knowledge about the endangered state of the planet, or risks associated with climatic changes, all removed from individuals' direct living environment, are affecting their perception of environmental quality. The influence of the perceived quality of a distant environment on perceived quality of an immediate environment must be taken into account.

One of the main issues in this area is the attainment of optimal congruence between the criteria of objective and subjective environmental quality. Frequently, different methodological approaches are used and different results are obtained. One of the main challenges for the future is to develop assessment combining objective and subjective measures of environmental quality. This strategy could be helpful in obtaining more reliable and valid measures of perceived environmental quality.

In addition, the importance of identifying groups of specialized environmental users must be underlined and considered when designing perceived environmental quality assessment strategies. Different age groups and cultural differentiation must be taken into account.

Perceived environmental quality standards that consider an individual's total environmental assessment are necessary from a conceptual point of view (Gärling, 1998; Stokols, 1995). Perceived environmental quality assessment must assume the operational management of a complex unit, as represented by the person-in-the-environment. It must be understood as a person or group's set of relatively stable perceived qualities of a physical and/or social environment (Clitheroe, Stokols & Zmuidzinas, 1998: 105).

Finally, the importance of connecting perceived environmental quality assessment to the decision-making processes of planners and decision makers must be emphasized so that research can fulfil one of the fundamental objectives that justify it: the improvement of the human environment and the realization of an optimum level of human well-being.

PERFORMANCE

INTRODUCTION

Performance assessment is a class of testing that purports to measure individual and team ability to display complex knowledge and skills. This entry will describe attributes and uses of performance assessments, discuss some technical issues, and point to likely approaches using technology to strengthen their utility. Performance assessment can take many forms, including observed actions (either live or recorded) of the examinee(s), the evaluation of products and related processes created by the respondent(s), or the conduct and outcome of multiple-stage projects. Performance assessment can focus on the output, or end result, or attend to the procedures by which a goal is accomplished. The stimuli eliciting a performance can be many, including simple verbal directions, printed text, computer-supported stimuli, or other agreed-upon signals.

Although performance assessment has sometimes been defined in the negative – as 'not paper and pencil' or not multiple-choice test format – it is very possible that a given performance assessment might incorporate many types of response formats. The main idea in performance assessment is to get an integrated sample of student accomplishment, usually one that requires substantial time to produce. Performance assessments, like other tests, can be administered on a stand-alone basis

at a particular interval, such as the end of the year, or can be integrated more directly into instruction. A collection of performances, creating a portfolio of a student's performance, can be constructed. These portfolios could either document emerging expertise over a period of time or contain a sample of best pieces to show the highest level of performance of which the student is capable. Common attributes of performance assessments are:

- Extended format
- Applied domain
- Complex task
- Constructed response
- Rated or judged scores

While predominantly used to draw conclusions and make decisions about individuals, performance assessments have been used to measure team processes in school, military, professional, and business settings. One such approach that has received much attention in team research is low-fidelity networked simulations (Bowers, Salas, Prince & Brannick, 1992; Weaver, Bowers, Salas & Cannon-Bowers, 1995). These assessments enable teams of individuals to perform a collaborative task, with individually defined responsibilities, using a networked computer environment. Examples of this type of assessment include evaluations of aircrew coordination (Salas, Bowers & Cannon-Bowers, 1995) and team negotiation practices and processes (O'Neil, Chung & Brown, 1997).

The advantages of this form of team performance assessment are many. Notably, these assessments can be achieved at a relatively low cost, particularly in comparison to full-scale simulations or live administration. In addition, such assessments provide for increased experimental control of independent variables in team research. They provide a means to facilitate the breadth and depth of research in the area of team performance assessment. Moreover, these assessments provide a method for the generation and testing of team performance theory (Weaver et al., 1995).

Finally, team performance assessments provide an effective platform for the investigation of the psychometric properties of various team effectiveness measures. There is converging research to support the reliability and validity of low-fidelity networked simulations as a research tool in the investigation of assessing team performance (Bowers et al., 1992).

The purpose or purposes for which a performance assessment is developed and used will guide the degree to which technical standards should be applied to make a judgement of its quality and validity (*Standards for Educational and Psychological Testing*, American Educational Research Association, American Psychological Association, and National Council on Measurement in Education, 1999). To the extent that comparisons from the data will be drawn among different students, classrooms, programmes or institutions, standardized approaches should be used to assure comparable administration. For example, performance assessments used as part of classroom learning may be developed by a teacher group and judged according to very malleable standards or guidelines. On the other hand, if a performance assessment was key in determining whether a student received a diploma or was admitted to a competitive programme, every effort would need to be made to ensure that the assessment was administered carefully and that raters were trained to provide valid scores.

WHAT IS KNOWN ABOUT PERFORMANCE ASSESSMENT?

Considerable research has been undertaken with regard to performance assessments, and although some findings are robust, others are in need of continued exploration. While most results have implications for the quality of the information resulting from the assessment, they may also be pertinent to practicality and utility issues.

Scoring Rubrics

At the outset of the most recent revival of performance assessments, *c.*1989, there was a belief that every new topic and task required its own specially constructed set of scoring guidelines. After considerable research, performance assessment has converged on an approach that uses general categories that are independent of particular domains (e.g. the use of prior knowledge), as well as elements that are domain specific (e.g. use of a split-half approach in troubleshooting electronic malfunctions). In addition, contention has subsided around whether rubrics should be

analytical – that is, composed of numerous subscores – or holistic, producing only one score although requiring the rater to attend to different aspects of performance. Of more importance is the extent to which scores can give a reliable estimate of student performance. When analytical approaches are well designed, it is possible that they can provide information useful for targeted instructional improvement.

Task Generation

There is good evidence that performance assessments can be developed at relatively low cost with an aid for clear task specifications. In research conducted in the state of Hawaii and in numerous local school districts, task formats were designed that facilitated the substitution of new content and increased the likelihood of generalizable results. For example, a task format asking students to examine opposing interpretations of historical events and to write about their interpretation to a friend can be applied at various grade levels and topics (Baker, Freeman & Clayton, 1991; Baker, Linn, Abedi & Niemi, 1996). An efficient means of comparable task generation is desirable since extended performance assessments are memorable, and, in a secure testing environment, may be obsolete after one administration.

Validity

Validity arguments are developed for all measures based on their purposes and the degree to which their use adheres to developers' recommendations. When performance assessments first became popular, there was a notion that they might be exempt from the 'usual' standards of validity and reliability associated with more traditional testing forms. In the early 1990s, writers attempted to clarify the requirements for validity for performance assessments used to estimate individual or school progress and accomplishments. In related works (Baker, O'Neil & Linn, 1993; Linn, Baker & Dunbar, 1991), criteria for evaluating the quality and validity of performance assessments have been proposed.

Most of these criteria are expanded in the *Standards for Educational and Psychological Testing* (American Educational Research Association, American Psychological Association, and National Council on Measurement in Education, 1999). Of special note are the tensions among many of these criteria. For example, if performance assessments are to cover a good deal of content and promote transfer to new domains, they will usually call for higher levels of complexity.

However, these requirements set a high standard if simultaneously (and perhaps most importantly) the key attribute of validity for school-related tests is that they are susceptible to change caused by good instruction. As yet, there is relatively little evidence about the impact of opportunity to learn and achievement on performance assessments (Baker et al., 1995).

Fairness

For a test to be useful, its results should provide no particular advantage or disadvantage to identifiable groups of examinees. At the outset, performance assessment was thought to provide an additional opportunity for heretofore low-performing groups to demonstrate their competence. Unfortunately, the evidence suggests that minority students, in the US at least, seem to have higher rates of non-completion on open-ended responses (Abedi, Lord & Plummer, 1997: 33–37). In addition, although physical performance is often a component of a task (e.g. the weighing of unknown chemicals), most performance assessments have required far more integration of language skills with other subject matter skills. For example, tasks may be presented in extended verbal cues. Responses, even those focusing on problem solving or other action, may require written explanations. As a result, the concern about linguistic demands of tasks has led to a set of efforts in accommodating tasks for second language speakers. The intent is to maintain the challenge and subject matter integrity of the task without overburdening the examinee with unnecessary linguistic barriers.

Practical Constraints

There are numerous reasons for the recession in the use of performance assessments in educational policy environments. Many derive from an inappropriate view of the development costs of such assessments and from the fact that many

vendors charge substantial amounts of money for each examinee, for a relatively small amount of new data. In particular, when instruction has not yet become sufficiently effective to change the strongly skewed data that have been obtained from most performance assessment administrations, it is little wonder that policymakers may prefer less costly approaches to obtaining achievement data.

Nonetheless, one of the promises of performance assessment was that it might model more modern instructional approaches for teachers and students (Herman, Aschbacher & Winters, 1992). When tests that consist almost exclusively of short-answer or multiple-choice items are employed, it is not surprising to observe instructional practices that follow the lead of the test format. It is not unusual, therefore, for the argument for or against performance assessment to rise and fall on cost and practicality. Since performance assessments are generally more costly to score when compared with the optical scanning technology used to score multiple-choice tests, certain approaches to minimize these costs are under development.

One widely used approach involves the scoring of examinations by teachers, where teachers score the work of either their own or others' students. In environments with rapid turnover of teachers or where underprepared teachers are employed, the resulting quality of scoring is not high. Even when protections involving centralized scoring of a substantial proportion of papers are available, adjustments to teachers' scores can be made only to groups and not to individual papers. Thus, such strategies are not useful in the realm of high-stakes testing. Another approach is to use computer-based algorithms to score student papers, and a number of commercial ventures exist to do this. The task is based on a set of prescored papers; the computer-scoring algorithm typically uses a complex regression model to develop scores similar to the operational criteria used by the person-scored system. Thus far, such systems are used only to confirm live rater judgements rather than to supplant them.

Technology

The use of technology obviously has much to offer in the support of performance-based measurement. Technology is already used in assessing students' ability to solve problems in simulated environments, to use expert approaches to search databases and the Web, and to solve collaborative problems. In addition to automated scoring of essays, there are other expert-based approaches to evaluating student online performance.

In addition, automated authoring systems linked to databases of content will enable the construction of comparable tasks with the aid of computers and serve to improve the validity of the assessments as well as to reduce task development and administration costs.

Psychometric Issues

Performance assessments have been criticized for lacking generalizability due to large rater effects in variance decomposition analysis. However, study after study has established that raters can be trained to evaluate student work reliably. Old notions that every performance needs to be scored by at least two raters (and sometimes more) are not supported by the literature, which repeatedly suggests that one well-trained rater may be enough for most assessment purposes (e.g. programme evaluation, system monitoring, instructional improvement, student feedback). Investing in careful training procedures (Baker, Aschbacher, Niemi & Sato, 1992) can reduce administration costs in the long run. Further, researchers have noted that 'quite high levels of generalizability across raters can be achieved when well-defined scoring rubrics are reinforced by intensive training and ongoing monitoring during rating sessions' (Linn & Burton, 1994: 5).

In addition to addressing concerns about lack of generalizability due to rater inconsistency, research has focused on the task-specific nature of performance assessments. Cronbach states, 'The emphasis in performance assessment on tasks requiring extensive working time makes it very difficult to hold down measurement errors associated with task specifics' (Cronbach, Linn, Brennan & Haertel, 1997: 398). Score reliability is also related to the number of tasks that can be said to come from the same domain. Early generalizability studies (Shavelson, Baxter & Gao, 1993) documented that low generalizability among tasks resulted when task characteristics differed. What remains to be seen is whether such generalizability can be reduced by appropriate

instruction directed to the domain from which the tasks are sampled. Unless this is possible, the idea of considering many performance tasks as samples from the same domain would be easy to challenge.

When scores on performance assessments are to be used to classify students with regard to standards, then the likelihood of misclassification as a function of low reliability should be considered. Psychometric researchers have suggested that the standard error (SE) rather than a reliability coefficient should be used to describe the uncertainty associated with the score on performance assessments (Cronbach et al., 1997; Yen, 1997). If scores on performance assessments are used to classify a school or other institution, matrix-sampling designs can help reduce the error in school-level scores resulting from task specificity. However, these designs will not reduce task-specific error in individual-level scores. In addition, score reports for school-level scores should include the per cent of respondents above a designated cut-point (PAC) as well as the standard errors for the PACs.

CONCLUSIONS

Performance assessment is a technique for testing that has notable benefits in its direct connection to learning and theories underlying the development of competence. Technical and practical problems including managing the assessment and assuring high technical quality are yet to be fully resolved.

The psychometric research on performance assessments is not fully conclusive, nor should it be considered complete. As Cronbach and colleagues have recently stated, 'evaluating the uncertainty of assessment results taxes our present psychometric understandings. Thus, more research on technical dilemmas involved in new assessment protocols is urgently needed' (Cronbach et al., 1997: 398).

PERFORMANCE STANDARDS: CONSTRUCTED RESPONSE ITEM FORMATS

INTRODUCTION

When standard-setting methods were initially developed, most of the assessments consisted of selected-response or multiple-choice items. These methods most often focused on judgements by experts on the probable item-level performance of examinees. For example, the Angoff (1971) standard-setting method asks panellists to estimate the probability that a randomly selected, hypothetical 'minimally competent candidate (MCC)' would be able to answer items from the test correctly. The Nedelsky (1954) method focuses the panellists' judgements on the alternatives comprising multiple-choice questions, asking panellists to identify those alternatives that the MCC would be able to eliminate as incorrect. The probability of an MCC getting the item correct is calculated as a function of the number of remaining options. Obviously, these kinds of methods will not work very well with constructed-response items.

CONSTRUCTED-RESPONSE QUESTIONS

Currently, many assessments contain open-ended questions, either in the form of written essays, oral response, portfolios, observations of performance by scorers of real or simulated patients, or through structured patient management protocols. An important consideration when setting cutscores with constructed-response assessments is the total number of constructed-response questions that comprise the assessment package and the complexity of these questions. In some assessments, the number of constructed-response questions is fairly small (between 5–10) and for others, the number is much higher (15–20 or more).

The magnitude and complexity of the total assessment has implications for the utility of some of the standard-setting approaches used with constructed-response assessments. If the total number of questions and the complexity of these

responses are somewhat limited, procedures that seek a holistic decision about the overall performance of the candidates can be used. When the number of questions is high, the capability of the panellists to make a holistic judgement about the overall performance becomes more difficult. In such cases, strategies need to be employed that use the information on the individual questions to set an overall performance standard. One such approach is to set individual performance standards on the separate questions and then to aggregate these performance standards question-by-question to obtain the cutscore on the full test.

QUESTION-BY-QUESTION METHODS

Several approaches use this question-by-question (sometimes referred to as an exercise-by-exercise) approach. A prevalent strategy employed with constructed-response questions uses an analytic analysis of the probable performance of a typical MCC. In many of these applications, the scoring guidelines identify positive points for specific responses. In addition, negative points can be accrued through making anticipated mistakes. Through an analysis of the anticipated performance of the MCC, combining positive and negative points, the expected score for the MCC is obtained for the question. An aggregation of these question-level expected scores across all the questions in the test serves of the cutscore for the test.

Hambleton and Plake (1995) used extended Angoff approach to have panellists estimate, for five questions scored on a 1–4 point scale, the anticipated score of the MCC. Next, panellists were asked to weight each of the 5 questions, where the weights represent the relative importance of that question to the overall purpose of the assessment. The product of the question's weight and the anticipated score for the MCC on that question was aggregated across the 5 questions to form an overall weighted minimum passing score. This approach attempts to focus the final cutscore not only on the anticipated performance of the MCC on the individual questions, but to take into account the total makeup of the examination in a more holistic sense. Through their weights, panellists can identify more important questions to receive relatively higher emphasis in the final pass/fail decision.

Another method is the 'paper selection' or 'Benchmark' approach. Under this paradigm, panellists are asked to select from a set of examinee performances, the work that best typifies the performance of the MCC. In some applications, the scores on the work are revealed to the panellists, but this is not always the case. The task presented to the panellists is to select two papers from the set of 'Benchmark' papers that either represent or bracket the anticipated performance of the MCC. Panellists' aggregate results are presented to the panel, often followed by discussion, and then the panellists make a revised estimate of the performance of the MCCs on this question. Their average value is used as the cutscore for the question. The process is repeated for each question that comprises the assessment. The final cutscore is determined by summing the results across the questions in the assessment. Critical to the success of this approach is the quality of the Benchmark papers and how well they represent their intended score point.

Another method, called the Analytical Judgment Method or AJM (Plake & Hambleton, 2001), is a judgemental procedure that focuses panellists' attention on actual student work. The panellists' task is to classify student papers into one of several performance categories defined to capture levels of performance as expressed by the multiple performance categories. The classification scale consists of several categories, for example Below basic, Borderline basic, Basic, Borderline proficient, Proficient, Borderline advanced, Advanced. With the AJM, each of the questions that comprise the assessment is considered independently by the panellists. For each question, the panellists review each of several (usually 50 or more) student papers, sampled to present the full score continuum, and are asked to make categorical assignments regarding the performance levels represented by the quality of the student's work. Student papers are not presented in the same order across the questions. The panellists do not know the author identification of the student's work, so the panellists are not able to make a total judgement about the overall work of an individual student; rather the panellists classify the papers for the students independently for each of the test questions. Scores for papers that were assigned to the borderline categories are used in deriving the cutpoints.

HOLISTIC APPROACHES

Some methods attempt to capture the totality of the examinees' performance by considering their overall examination performance. As mentioned above, the utility of these approaches is limited to programmes whose assessments allow for a meaningful conceptualization of the totality of the candidate's performance. Often this involves assessments with a limited number of constructed-response questions.

One approach that addresses the holistic nature of the examinee's performance is the Judgmental Policy-Capturing (JPC) Standard Setting Method (Jaeger & Mills, 2001). Panellists make classification decisions concerning the overall quality of examinee performance based on profiles of scored performances across all questions or tasks. One application, used in an operational standard setting with the National Board for Professional Teaching Standards certifications, involves a 1–4 point scale for overall candidate performance where, in general, a '1' represents unacceptable performance that clearly does not warrant Board certification, a '2' indicates a candidate performance that is inadequate for Board certification, a '3' represents performance that satisfies the criteria for Board certification, and a score of '4' signals exemplary performance that exceeds the performance criteria for Board certification. It is expected that the final standard would fall in the region of the overall scale that represents performance that is consistent with criteria for National Board Certification.

After training on the nature of the exercises and the meaning of the scores, panellists are trained in the use of the policy-capturing methodology. Through a series of iterations, panellists are asked to make and, perhaps, modify their classification decisions on a large number of candidate performance profiles. Based on a regression algorithm that attempts to capture a compensatory decision model that is consistent with each of the panellist's policy, weights are derived to be used in calculating a weighted average overall performance score for each candidate. The median of panellists' captured policies can be used in developing a performance standard. Candidates with overall performance scores above the standard would receive certification, and those with scores below the standard would not. The final decision of the location of the performance standard involves another step where panellists focus on the profiles and overall performance scores that are in the vicinity of the scale-implied cutscore (e.g. close to 2.75). The final choice of the cutscore is then determined by the panellists' judgement of the minimally acceptable overall performance score for Board certification.

Another approach that considers the profile of examinee performance is the Dominant Profile approach, developed by Plake, Hambleton, and Jaeger (1997). This approach involves having panellists, who are fully cognizant of the exercises and the meaning of the exercise scores, derive decision rules that capture their view of the score levels across the profile components necessary to pass the test. Under this approach, panellists can articulate decision rules that are complex and reflect mixed decision models. For example, they could set a conjunctive rule for part of the profile (a minimum score on a particular question) and compensatory rules for other parts. Once the decision rule for the 'just barely acceptable' profile is established, any profile that has scores that meet or exceed that profile are deemed to 'pass'. Therefore, these 'dominating profiles' are those that represent passing scores whereas other profiles of scores would be deemed as failures.

The Bookmark (Mitzel et al., 2001) approach also has the panellists consider the full test, but the test questions have been ordered on difficulty. This method is used most often with tests that are comprised of a mixture of multiple-choice and constructed-response questions. An item-response theory method is used to scale the questions (both multiple-choice and constructed-response) onto a common scale. The panellists' task is to locate in this ordered test booklet the location where a minimally competent examinee would be expected to answer the preceding items correctly and the subsequent items incorrectly. Panellists' results are discussed between rounds, with panellists providing their rationales for the locations of their bookmarks. Typically, three rounds are conducted and convergence in bookmark location usually occurs across the rounds. An average of the panellists' round 3 bookmark location is used as the recommended minimum passing score.

The Body of Work (Kingston et al., 2001) approach involves having panellists sequentially

view full test booklet response for examinees at varying score levels. Initially, panellists examine test booklets from a broad range of examinee performance. Based on their analysis of these test booklets, more test booklets are provided to them to consider, this time from a narrower range of score performance. In the final round, panellists classify student test booklets in pass (1) and fail (0) categories. The minimum passing score is determined by using logistic regression. The test score where the probability of passing is 0.5 is selected as the minimum passing score based on the Body of Work approach.

In summary, a variety of standard-setting approaches have been developed for use with constructed-response questions. One method involves focusing on the questions one at a time and setting a minimum passing score on that question. Combining the individual question-by-question minimum passing scores is then typically used as the overall examination cutscore. The minimum passing scores are typically determined by having the panellists either go through an analytical process of identifying the points on the question that would be expected to be earned by the MCC or by selecting from Benchmark papers the work that exemplifies that of an MCC.

A few methods have attempted to use a more holistic, full examination, approach by focusing the standard-setting process on examinee score profiles. These methods have been used typically with assessments that have a small number of questions. These approaches allow for the totality of examinee performance across the specific questions to be the basis for the performance standard.

EVALUATING THE RESULTS FROM A STANDARD-SETTING ACTIVITY

One of the most challenging parts of a standard-setting activity is knowing whether the results are appropriate. There is no 'gold standard' to aid in knowing if the performance standard is 'right' or not. Instead, the validity of the performance standard is judged by evaluating the results from the standard-setting workshop. Kane (1994) provided a framework for evaluating the validity of a performance standard (procedural, internal, and external). In addition, Hambleton (2001) presents a series of questions that should be considered in evaluating the results from a standard-setting activity. These 20 questions are:

1 Was consideration given to the groups who should be represented on the standard-setting panel?
2 Was the panel large enough and representative enough of the appropriate constituencies to be judged suitable for setting performance standards?
3 Were two panels used to check the generalizability of the performance standards?
4 Were sufficient resources allocated to carry out the study properly?
5 Was the performance standard-setting method field tested in preparation for its use in the standard-setting study, and revised accordingly?
6 Was the standard-setting method appropriate for the particular assessment and was it described in detail?
7 Were panellists explained the purpose of the assessment and the uses of the test scores at the beginning of the standard-setting meeting?
8 Were the qualifications and other relevant demographic data about the panellists collected?
9 Were the panellists administered the assessment, or at least a part of it?
10 Were the panellists suitably trained on the method to set the performance standards?
11 Were descriptions of the performance categories clear to the extent that they were used effectively by panellists in the standard-setting process?
12 If an iterative process was used for discussing and reconciling rating differences, was the feedback to panellists clear, understandable, and useful?
13 Was the process itself conducted efficiently?
14 Were the panellists given the opportunity to 'ground' their ratings with performance data and how was the data used?
15 Were panellists provided consequential data (or impact data) to use in their deliberations and how did they use the information?
16 Was the approach for arriving at final performance standards clearly described and appropriate?
17 Was an evaluation of the process carried out by the panellists?

18 Was evidence compiled to support the validity of the performance standards?
19 Was the full standard-setting process documented?
20 Were effective steps taken to communicate the performance standards?

These questions are not specific to standard-setting methods for constructed-response assessments, but are applicable to standard-setting methods in general. Some of them are more challenging to meet with complex performance assessments, such as question no. 9 which asks whether the panellists were administered the assessment. For some complex performance type assessments, it would be unrealistic to ask the panellists to engage in the actual assessment activities. However, it is important that the panellists have a deep appreciation of the complexity and difficulty level of the tasks that the examinees are being asked to complete for the assessment.

FUTURE PERSPECTIVES AND CONCLUSIONS

The purpose of this entry was to identify standard-setting methods that are appropriate to use with assessments that ask the examinee to complete tasks, such as an essay examination, a performance task, or a portfolio. Most of the long-standing standard-setting methods (such as those proposed by Angoff and Nedelsky) were designed for multiple-choice assessments. Although it is possible to extend some of these approaches for use with constructed-response assessments, that is not always the case. This is particularly true with complex performance assessments.

In this document, several methods for use with constructed-response assessments were described. These methods were differentiated based on whether they considered the parts of the assessment analytically or holistically. Overall, these methods are designed to provide indications of appropriate performance standards or cutscores that are congruent with the complexity and difficulty of the tasks presented to the examinees. Because there is no 'right' answer of 'gold standard' to use in evaluating the outcomes of a standard-setting activity, evaluation criteria are presented the question of the reasonableness and appropriateness of the panel convened, the methods used, and the results.

PERFORMANCE STANDARDS: SELECTED RESPONSE ITEM FORMATS

INTRODUCTION

Setting performance standards means implementing a process that identifies one or more points on a score scale to create categories of observed test scores. More fully, Cizek (1993: 100) has defined standard setting as 'the proper following of a prescribed, rational system of rules or procedures resulting in the assignment of a number to differentiate between two or more states or degrees of performance'. This differentiation can result in dichotomous classifications such as Master/Non-master or Pass/Fail. Standard setting can also result in more than two categories or achievement levels, such as Basic/Proficient/Advanced or the familiar grades of A, B, C, D, F.

In practice, setting a performance standard has become nearly synonymous with deriving one or more cutting scores. However, as Kane (1994) has pointed out, 'it is useful to draw a distinction between the *passing score*, defined as a point on the score scale, and the *performance standard*, defined as the minimally adequate level of performance for some purpose ... The performance standard is the conceptual version of the desired level of competence, and the passing score is the operational version' (p. 426, emphasis in original).

Specialists in the field of educational measurement have developed numerous methods for deriving levels of performance and a wide variety of applications for standard-setting methods exists. Standards are established for determining school readiness; for communicating student achievement in school subjects; for granting admission to institutions; for selection for special services; for suggesting diagnoses or treatments, for placement into specialized programmes; and for awarding certification or granting licensure. Overviews of the many approaches to standard setting can be found in several sources (see, e.g., Berk, 1986; Cizek, 1996a, 2001; Jaeger, 1989; Livingston & Zieky, 1982).

Although the methods for standard setting are numerous, care must be taken to match the method used to the particular characteristics of the assessment and context in which the standard setting is conducted. Linn (1994) has suggested that standard-setting procedures can be distinguished based on the four unique purposes of exhortation, exemplification, accountability, and certification of achievement. It is also common to categorize methods as reflecting *absolute*, *relative*, or *compromise* standards. Jaeger (1989) has grouped standard-setting methods into two categories, those which are *test-centred* and those which are *examinee-centred*.

It can also be useful to classify standard-setting methods by the response format dictated by the items or tasks comprising the assessment, i.e. either *constructed-response* or *selected-response* formats. The remainder of this entry consists of two major sections: a review of some of the most common methods for establishing performance standards on selected-response (e.g. multiple-choice) assessments; and a brief summary of professional guidelines for doing so.

STANDARD-SETTING METHODS

The following subsections describe major standard-setting methods that have traditionally found wide use on assessments comprised of selected-response format items. The methods are described in order of their introduction in the psychometric literature. All but one of the methods that will be described (Nedelsky) can be – and have been – fairly easily adapted to tests consisting of other item/task formats. Conversely, many newly introduced methods have been developed specifically for use with tests consisting of constructed-response items/tasks. Two such examples would be the Bookmark method (Mitzel, Lewis, Patz & Green, 2001) and the Analytic Judgment method (Plake & Hambleton, 2001). It is also important to note, however, that nearly all of the newer methods

could be applied to tests consisting of a mix of item formats, or even to tests consisting exclusively of selected-response items.

The Nedelsky Method

The method introduced by Nedelsky (1954) involves assigning values to multiple-choice test items based upon the probability of examinees being able to rule out incorrect options. Nedelsky introduced the concept of hypothetical, minimally competent examinees. Nedelsky used the term *F-D student* to refer to those persons who were on the borderline between receiving a course grade of F (failing) or D (passing). By extension, Nedelsky's conceptualization has been extended to applications involving examinees who are on the borderline of being considered competent or not competent, licensable or not licensable, adequately prepared for professional practice or not, and so on.

To use the Nedelsky method, standard-setting participants begin by discussing (and, commonly, by reaching consensus about) the characteristics of the hypothetical minimally competent examinee in the area covered by the test. Then, relying on that conceptualization, participants carefully inspect each item in the actual test form that will be administered to the examinees. For each item in the test, standard-setting participants identify all options that a hypothetical minimally competent examinee would rule out as incorrect. The reciprocal of the remaining number of options is each item's *Nedelsky value*. Under the assumption that a minimally competent examinee would rule out the obviously incorrect options and guess at random from the remaining options, the Nedelsky value for an item can be thought of as representing the probability that such an examinee will answer the item correctly. For applications involving five-option multiple-choice items, Nedelsky values can range from 0.20 (no options could be ruled out as obviously incorrect) to 1.00 (all options but the keyed response could be ruled out). In most applications, the sum of the Nedelsky values across all test items is used as the passing score.

When a panel of standard-setting participants is used, group consensus about each item's Nedelsky value may be pursued to arrive at a single rating for each item. Or, the average of participants' individual ratings could be used as the rating for each item. A final option would be to sum the probabilities across items for each participant (yielding a recommended passing score for each participant), then calculate the average of the individual passing scores.

The Nedelsky method has the advantage of computational simplicity, and it is easy for participants to understand and apply. However, it appears to be used infrequently compared to other methods, and limitations of the method may be one reason for this. For example, Berk (1984) has noted that the scale of Nedelsky values does not permit probabilities between 0.50 and 1.00. Shepard (1980) has hypothesized that this restriction and the fact that participants are often reluctant to assign Nedelsky values of 1.0 may explain why the Nedelsky method often results in standards that are lower than those obtained using other methods.

The Ebel Method

A method proposed by Ebel (1972) also requires participants to make judgements about each item in a test, and also relies on the conceptualization of the minimally competent examinee. To implement the Ebel method, participants provide estimates of the difficulty of individual test items, judgements about the relevance of the items, and predictions about examinees' success on combinations of the difficulty and relevance dimensions. Ebel proposed that participants categorize items according to four levels describing their judgements about the relevance of each item for distinguishing successful overall performance in the area covered by the test (Essential, Important, Acceptable, Questionable) and three levels describing the participants' judgements about item difficulty (Easy, Medium, Hard). Participants then make judgements about the per cent of items correct in each relevance-by-difficulty category that should be required of the hypothetical minimally competent examinee group in order to pass the test. The recommended passing score resulting from application of the Ebel method is found by first multiplying the number of items in each relevance-by-difficulty category by the per cent of those items judged to be necessary for passing. These products are then summed and the sum is divided by the total number of items to yield a recommended passing score.

Although the Ebel method is conceptually and computationally simple, it has also received criticism. For example, the method reveals inadequacies in the test construction process (e.g. Why should any item judged to be of questionable relevance be included in an examination?). It requires judgements that may not be necessary (e.g. empirical item difficulty values are often available).

The Angoff Method

The method developed by Angoff (1971: 514–515) has proven to be one of the most popular methods for setting standards on tests comprised of selected-response items. The method, and its many variations, has also been adapted to tests consisting of other than selected-response format items (see, for example, Hambleton and Plake's [1995] description of an 'extended Angoff procedure' to set standards on performance assessments, or Loomis and Bourque [2001] for application of a modified Angoff approach on the National Assessment of Educational Progress).

Like the other item-based procedures, the Angoff method requires standard-setting participants to review each item in a test form and to provide judgements regarding the performance of minimally competent examinees. The unique aspect of the Angoff method is that the judgements participants make are in the form of estimated percentages of the minimally competent group that will answer each item correctly. Thus, ratings provided by participants using the Angoff method can range from 0 to 100. In practice, however, the lower end of the range is usually set at the chance level; for example, on a five-option, multiple-choice item, the lower bound of Angoff ratings would be 20.

In most instances, Angoff's originally suggested procedure is modified to include two or more rounds of ratings as a way of reducing interrater variability. Participants (sometimes called *judges*) are also often provided with normative data (in the form of item *p*-values) or consequence data (in the form of anticipated pass/fail rates) in one or more of the rounds of ratings. (Modifications like these are often incorporated in other standard-setting methods as well.)

The Contrasting Groups Method

In contrast to procedures that require participants in the standard-setting process to make judgements about test items, examinee-centred methods require participants to make direct judgements about persons. Those judgements are combined with information about the actual performance of the same group of persons on an examination. One such method is known as the *contrasting groups* method (see Livingston & Zieky, 1982). The method involves asking participants, who have knowledge of both the examinee population and the knowledge or skill level judged identified as 'mastery' or 'passing' in the area tested, to classify a sample of examinees as either competent or not competent. This group of examinees is also administered the actual examination that will be used for decision making. This process permits the formation of two distributions of test scores: one for those judged to be 'masters' and one for those judged to be 'non-masters'.

To set a cutting score using the contrasting groups method, the two distributions of test performance are examined to find a point on the score scale, usually the point at which the tails of the master and non-master distributions overlap. Livingston and Zieky (1982: 40) recommend that the test score distributions of these contrasting groups then be plotted and smoothed. To derive a passing score, they recommend that 'one logical choice is the test score for which the ''smoothed'' percent-qualified is exactly 50 percent'.

The Borderline Group Method

The borderline group method is another example of an examinee-based procedure. Zieky and Livingston (1977) proposed using a single group judged to be at the borderline separating competent from non-competent performance. Like the contrasting groups procedure, the borderline group method requires participants who are familiar with the range of examinees' knowledge and skill. Judgements are made regarding which examinees are on the 'borderline' between competent/not competent or pass/fail, and a sample of examinees is administered the actual test form that will be used for decision making. The median score of this subsample of examinees judged to be 'borderline' is used as a recommended standard.

The Hofstee Method

Some standard-setting methods blend information about absolute levels of knowledge or skill

required of examinees and normative judgements about acceptable pass/fail rates. One such method was suggested by Hofstee (1983) who observed that important classification decisions are 'based on two classes of premises, one political and the other cognitive' (p. 109). Because methods like Hofstee's represent an attempt to strike a balance between these competing perspectives, they are sometimes referred to as 'compromise' methods.

The Hofstee method is implemented by asking each standard-setting participant to respond to four questions:

1 What is the lowest cutoff score that would be acceptable, even if every student attained that score on the first testing?
2 What is the lowest acceptable cutoff score, even if *no* student attained that score on the first testing?
3 What is the maximum tolerable failure rate? and
4 What is the minimum acceptable failure rate?

These mean values, over judges, associated with responses to these four questions are referred to, respectively, as k_{min}, k_{max}, f_{max}, and f_{min}. A cutting score is derived by plotting a line through the points (f_{min}, k_{max}) and (f_{max}, k_{min}), projecting the line onto the distribution of observed test scores, and identifying the point of intersection. From that point, a line drawn perpendicular to the ordinate locates the per cent correct score required for passing; a line drawn perpendicular to the abscissa identifies the corresponding failure rate. Although proposed at a time when the primary application was to multiple-choice format tests, the Hofstee method (like other methods described here) may also be used on tests consisting of other item/task formats.

GUIDELINES FOR STANDARD SETTING

Each of the standard-setting methods described previously requires careful planning, execution, and evaluation in order to make a strong case for the stability and validity of the resulting cut-scores and classifications. An abundance of guidance exists for accomplishing these goals.

Of primary importance are the *Standards for Educational and Psychological Testing* (AERA/APA/NCME, 1999). Among other things, the *Standards* recommend that: 'the rationale and procedures used for establishing cut scores be clearly documented' (Standard 4.19, p. 59); cut scores 'should be established on the basis of sound empirical data concerning the relation of test performance to relevant criteria, (Standard 4.20, p. 60); and when a judgemental process is used, the process 'should be designed so that judges can bring their knowledge and experience to bear in a reasonable way' (Standard 4.21, p. 60). The *Standards* also provide recommendations for technical analysis and reporting. For example, the *Standards* recommend that conditional standard errors of measurement be calculated at cut points (Standard 2.14) and estimates of classification consistency (Standard 2.15) be reported.

A theoretical framework for gathering validity evidence for standard setting has been provided by Kane (1994). Kane identified three sources of evidence that should be pursued, including: (1) *procedural evidence* that 'focuses on the appropriateness of the procedures used and the quality of the implementation of those procedures' (p. 437); (2) *internal evidence* – that is, 'data generated within the standard-setting study itself that can be used as a partial check on the validity of the results' (p. 445); and (3) *external evidence*, in which investigators compare 'the results of decisions made using the passing score to the results of the same kind of decision, or a related decision made in a different way' (p. 448).

A number of authors have also provided practical guidelines for designing, conducting, and evaluating standard-setting procedures. For example, Cizek (1996b) outlined four types of information that should be reported when standard setting is conducted. These include information on: (1) the purpose of the test and the standard setting, including definitions of relevant constructs; (2) the standard-setting method used, including linkages between method and purpose, and linkages between method and the characteristics assessed; (3) the procedures as implemented, including description and rationale for adjustments to participants, judgements, or final results; and (4) technical analysis, including process and qualifications of participants, evidence that participants correctly applied the method, and estimation of variability in results.

A second source of practical guidance is provided by Hambleton (2001). Hambleton

presents 20 key questions that can be used to guide the conceptualization and planning of a standard-setting study, and can also be used to assess the procedures and results of a process that has been implemented. A particularly helpful aspect of Hambleton's work is the inclusion of several tables and forms that provide templates that are easily adapted to a wide range of standard-setting contexts. These include: (1) a list of steps common to all judgemental standard setting; (2) examples of sound performance level descriptions; and (3) a sample participant evaluation form.

CONCLUSIONS

Both the theory and practice of standard setting have developed rapidly over the past 40 years, as measurement specialists have provided rational, systematic solutions to the practical testing problem of setting performance standards. Regardless of the method used, however, the practice of standard setting involves human judgement – it represents the nexus of research design, statistics, instructional design, values, and policy considerations.

The standard-setting methods described in this entry were developed primarily for setting performance standards on assessments comprised of selected-response formats. Each of the methods provides a set of procedures that has been subjected to scholarly scrutiny and, if followed carefully, can yield defensible cutting scores. However, the requirement that *any* procedure must be carefully designed, executed, and evaluated cannot be overemphasized. As others have frankly observed: 'You can't fix by analysis what you bungled by design' (Light, Singer & Willett, 1990: viii).

Finally, it should be noted that standard-setting procedures are not an end in themselves. The cutting score that results from implementation of a standard-setting procedure is usually only a *recommended* standard. Ultimately, the entity with the authority to establish a standard of performance must review, reject, adjust, or approve the results of any standard-setting process.

PERSON/SITUATION (ENVIRONMENT) ASSESSMENT

INTRODUCTION

This entry gives an overview of the importance of person/situation interaction for the psychological assessment of either persons or situations, and provides guidelines for the assessment of person/situation interaction.

Any individual's specific behaviour such as a stress reaction varies across situations and can be graphically represented as an intraindividual situation profile of that behaviour. A behaviour shows a person/situation interaction if different individuals vary differently across situations in that behaviour (graphically: their situation profiles are not parallel). In such a case, the interindividual differences within situations are not consistent across situations; hence the behaviour correlates lower than 1 between the situations.

Figure 1 illustrates three typical cases: (a) no person/situation interaction between situations 1, 2 (note that the curves of the two individuals differ, however, in the level of the behaviour); (b) ordinal person/situation interaction between situations 2, 3 due to a ceiling effect (the interindividual rank-order is constant across situations but the sizes of the interindividual differences vary); (c) disordinal person/situation interaction between situations 3, 4 (the interindividual rank-order varies across situations; graphically, the profiles cross).

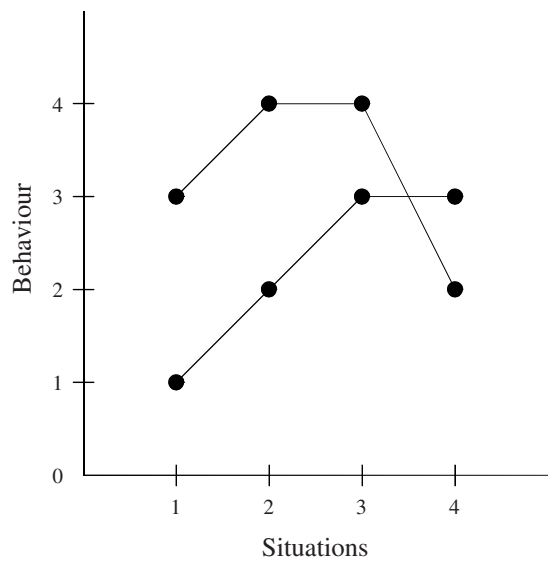

Figure 1. Three typical cases of (no) person/situation interaction. The two curves refer to two individuals (see text).

IMPORTANCE OF PERSON/ SITUATION INTERACTIONS

The importance of person/situation interaction for the assessment of personality traits was first recognized during the consistency debate in the 1970s and 1980s (Mischel, 1968; Kenrick & Funder, 1988). Single behaviours were found to show low cross-situational consistencies, which questioned the assumption of broad personality traits that would allow the prediction of behaviour in heterogeneous situations. However, these studies confounded person/situation interaction and measurement error, and hence overestimated the amount of systematic person/situation interaction. Empirical studies that have controlled measurement error by aggregating trait-relevant behaviour over time or across similar situations have found that the size of person/situation interaction varies greatly between different traits, from virtually zero interaction for subjective well-being to maximum interaction (equivalent to zero cross-situational consistency) for sociability in work versus recreational situations (Diener & Larsen, 1984). Thus, attempts to obtain general estimates of the percentage of variance attributable to persons, situations, and person/situation interaction (e.g. Endler & Hunt, 1966) are in vain.

Furthermore, it has been increasingly recognized that the size of person/situation interaction strongly depends also on the sampling of trait-relevant situations. Whereas it is relatively easy to obtain person samples that are representative of populations such as national age groups or applicants for particular jobs, it is still an unresolved issue how a representative situation sample should be obtained for a behaviour or a personality trait (Ten Berge & De Raad, 1999). The amount of person/situation interaction found will very likely depend on the heterogeneity of the situations in the situation sample. In addition, the extremity of the situations will also influence the amount of person/situation interaction because ceiling and floor effects induce ordinal interactions (see Figure 1).

Finally, person/situation interactions depend on whether an ecologically valid or an experimental design is chosen. In the first case, the frequency of persons in situations is controlled by the persons themselves such as in beeper studies that obtain at random times during the day reports of the current situation as well as experience or behaviour in the situation. In contrast, in experimental designs all persons are assigned to the same situations by the experimenter one by one, and are observed in them or are asked how they would react to them. The size of person/situation interaction tends to be smaller in ecologically valid designs to the extent that persons have opportunities to choose or to avoid certain situations.

An important approach to assessing situations that is often ignored in discussions of person/situation interaction is the definition of dyadic social interaction situations in terms of the interaction partner. People are important social stimuli, and social behaviour obviously varies according to the social role in the situation and to the relationship with the interaction partner. Although the sampling of the situations is much easier in this case, there are surprisingly few attempts to study person/role and person/person interactions systematically. The study of person/person interaction (a special case of person/situation interaction, not to be confused with social interaction!) is complicated by the fact that person B can be considered a situation for person A while person A can be simultaneously considered a situation for person B. Because persons cannot interact with themselves and because persons and situations are not statistically independent factors (e.g. friendliness will positively correlate between dyad members across dyads), traditional ANOVA or correlational methods are not valid in this case. Kenny and associates have developed the social relations model that distinguishes actor, target, and relationship effects (the latter correspond to person/person interactions), and proposed statistical tools for estimating these effects. This approach is increasingly used in person perception, dyadic relationship, and family research (Cook, 2000; Kenny et al., 2001).

So far, person/situation interactions have been discussed from the perspective of personality assessment. They put personality into context, or 'situationalize personality'. In addition, person/situation interactions are also important from the perspective of ecological psychology for the design of working or living

situations. Often, these situations are assessed in terms of mean responses of a person sample, treating the interindividual differences in the responses as error. For example, software engineers try to optimize computer menus for the average computer user. A more differentiated, yet rarely utilized approach is to 'personalize situations' by studying systematic person/situation interactions. For example, persons socialized with computers in the DOS era may rate keystroke menus more positively than younger users, or extroverts may enjoy wizards more than introverts.

SOME GUIDELINES FOR THE ASSESSMENT OF PERSON/SITUATION INTERACTIONS

Because the assessment of person/situation interaction is more costly than assessing only person or only situation parameters, it is useful to ask first whether person/situation interaction is large enough to be assessed at all. The answer depends on the samples of persons, situations, and behaviours that are to be assessed, and on whether the persons are able to select the situations. If the persons are placed into situations whether they like it or not, person/situation interactions are more likely to occur than when the persons can deliberately choose or avoid certain situations. In most cases, empirical studies will be necessary to evaluate the amount of person/situation interaction for the specific assessment task. Here it is crucial to separate person/situation interaction from measurement error, e.g. through aggregation over time or different behavioural indicators of the same construct.

If significant person/situation interaction is observed as indicated by a high ratio of person/situation variance divided by person variance in personality assessment, or a high ratio of person/situation variance divided by situation variance in situation assessment, this does not automatically mean that personality assessments have to respect situational information through the assessment of situation-specific traits, or that situation assessments have to respect personality differences through the assessment of situations for different personality types. Alternatively, the behaviour in situations can be predicted by broad, situation-unspecific traits, or broad, personality-unspecific situations; *a priori* it is not clear which strategy is the more efficient one.

What applies here is what Cronbach and Gleser (1957) called the bandwidth/fidelity tradeoff. This tradeoff means in the case of person/situation interaction that broad bandwidth traits (i.e. situation-unspecific traits such as 'sociable') predict behaviour in a wide range of situations with low fidelity (i.e. low predictive validity), whereas narrow bandwidth traits (e.g. situation-specific traits such as 'sociable with coworkers' or 'sociable with friends') predict behaviour in a limited range of situations with high fidelity (i.e. high predictive validity). In practice, this tradeoff boils down to a tradeoff between assessment costs and costs of incorrect predictions. If incorrect predictions are not very important (e.g. predictions of moral integrity for blue-collar workers), broad traits will often suffice, but if correct predictions are very important (e.g. predictions of integrity for diplomats), more costly assessments tailored to the various crucial situations are in order (see Shoda, 1999, for a detailed discussion of the utility of broad versus narrow traits in the prediction of behaviour). Similarly, even large interindividual differences in the reaction to a particular situation can be ignored in situation assessment if these differences are not consequential.

If person/situation interaction is significant and consequential, a good idea is to develop assessment tools and their interpretation around the notion of a situation profile. A classic example for such profile assessments is the Fear Survey Schedule (FSS) by Wolpe and Lang (1964) that assesses the intensity of fear reactions to various fear-arousing stimuli such as spiders, large groups of people, or medical examinations. Each person is assigned a profile, and persons with similar profiles can be grouped into homogeneous types through cluster analysis or similar procedures. Also, for personnel decisions, the similarity of a person's profile with a required profile can be quantified by computing the Euclidean distance to this standard profile, or it can be decided whether a person's profile falls into a predefined

range of acceptable scores around such a target profile.

If no such 'profiling tool' is available, it can be constructed in three steps: (a) exploring the range of relevant situations, (b) selecting a representative sample of situations, and (c) selecting one or more behavioural reactions that are ecologically valid for all selected situations. These reactions are then observed, or their likely occurrence is probed in an S-R inventory, modelled after the classic S-R inventory of anxiousness by Endler and Hunt (1966). If the situations are defined by concrete persons, or type of persons such as classmate or coworker, this approach leads to a person by relationship quality matrix that represents part of the individual's ego-centred network of social relationships (see Asendorpf & Wilpers, 1998, for an application of this approach). Similarly, situation assessments may be 'personalized' by profiles that plot a behaviour in the situation against different personality types.

FUTURE PERSPECTIVES

Desiderata for person/situation interaction assessment are (a) more research on the classification of psychologically relevant situations, (b) differentiating situation assessments by 'personalizing' the situations, (c) differentiating personality assessment by 'situationalizing' broad traits or factors such as the Big Five, particularly (d) respecting more the role and relationship specificity of behaviour in assessments of social traits, and (e) development of new models for the simultaneous statistical treatment of persons, situations, and behaviours (see Vansteelandt & Van Mechelen, 1998, for an interesting new approach).

CONCLUSIONS

Respecting person/situation interaction is not always necessary and often not wanted in the assessment of persons or situations because it increases assessment costs, but disregarding strong existing person/situation interactions can be even more costly by reducing predictive power too much.

OBSERVATIONAL METHODS (GENERAL), THEORETICAL PERSPECTIVE: BEHAVIOURAL

PERSONAL CONSTRUCTS

INTRODUCTION

Kelly's (1991) personal construct theory views people as constantly trying to give meaning to, and anticipate events in, their worlds. To do so, each individual develops a unique, hierarchically organized system of bipolar personal constructs, which provide a basis for the recognition of similarities and differences between events. Constructs which are superordinate in this hierarchy are assumed to be more important to the individual than those which are subordinate. Any attempt to understand an individual requires an assessment of their personal constructs, so that the world may, in effect, be glimpsed through their eyes. This entry will describe some of the methods which have been developed for this purpose.

ASSESSMENT METHODS

Repertory Grid Technique

Repertory grid technique is by far the most widely used method of personal construct assessment (See entry on 'Subjective Methods' in this volume). A set of 'elements', or aspects of the person's experience, is first elicited from the subject. These are usually significant people and aspects of the self, but this is not necessarily so, and numerous other types of element have been used: for example, relationships, life events, holiday resorts, and therapy sessions. A sample of the subject's constructs is next elicited, usually by presenting a series of triads of the elements and asking, for each triad, how two of the elements are alike and thereby different from the third. Since the technique is extremely flexible, there are numerous alternative ways of obtaining constructs, including free descriptions of the elements, interviews, structured methods designed for children, and supplying of the constructs by the investigator. Although the investigator who is only interested in obtaining a sample of the subject's constructs may not proceed to this stage, the final step in grid procedure is for the subject to sort all of the elements, usually by rating or ranking, in terms of all the constructs.

While some understanding of the subject's construct system may be obtained from visual inspection of the grid matrix, a much more detailed assessment is possible by the use of various computer packages, most of which include cluster and/or factor analyses, and some of which are interactive, eliciting a grid from, and providing feedback on its results to, a subject. Information may be derived from the grid on such areas as:

(i) the content of the subject's constructs, for which several coding systems are available;
(ii) the structure of the construct system, for example how 'tightly' or 'loosely' constructs are interrelated;
(iii) the particular relationships between constructs, which are assumed to indicate the personal meaning of these constructs;
(iv) distances (or degree of perceived dissimilarity) between particular pairs of elements.

In addition, most computer packages provide a spatial representation of the subject's construct system; and some allow the comparison of pairs of grids or the derivation of 'consensus', or modal, grids of a group of subjects.

Since there is no standard form of the grid, general statements about its psychometric properties are fairly meaningless, and in any case it has been questioned whether models derived from mental test theory are appropriate for the evaluation of grids. Nevertheless, various studies attest to the reliability and validity of certain grid measures in particular domains.

Amongst the numerous variations on grid technique are some which depart radically from Kelly's original procedure. One, which he himself developed, is generally referred to as the *Dependency Grid*, and involves asking the

subject to which of a list of people he or she would turn for help in various difficult situations. This allows, for example, an assessment of the extent to which dependencies are dispersed across a range of people. Certain grid procedures developed by one of Kelly's students, Hinkle, may provide an indication of the superordinacy of each construct elicited from the subject (Fransella & Bannister, 1977). In both the *implications grid* and the *resistance to change grid*, constructs fall along each axis of the grid. In the former, the subject is asked which other constructs in the grid are implied by each of their constructs; in the latter, each construct is paired with every other and the subject is asked on which he or she would prefer to shift from its preferred to its non-preferred pole. Various other grid procedures have been developed to explore particular domains of construing.

Autobiographical Texts

The other major assessment technique devised by Kelly was the *self-characterization*, in which the subject is asked to write an autobiographical sketch in the third person as if written by an intimate and sympathetic friend. Although qualitative methods of content analysis are usually applied to such sketches, there have also been attempts to derive quantitative indices from self-characterizations. As Feixas and Villegas (1991) have described, a more extensive autobiographical text may be transformed into a grid matrix of elements and constructs, to which a cluster analysis procedure may be applied.

Laddering, Pyramiding, and the ABC Technique

Hinkle's *laddering* procedure asks which pole of a particular construct a person would prefer to be described by and why, repeating the process for each new construct thus elicited (Fransella & Bannister, 1977). Although every construct in the ladder is assumed to be more superordinate than the preceding one, this assumption has not gone unchallenged. A converse procedure, *downward laddering*, in which the subject is asked, for each construct pole, how they would know that it applied to a person, was assumed by Hinkle to elicit subordinate constructs. As Fransella and Bannister (1977) note, this is also the aim of Landfield's *pyramid technique*, in which the subject is asked what kind of person is described by each pole of a construct, and what characteristics describe people who are the opposite of the new construct poles thus elicited.

A further method which traces the implications of a particular construct, and which is particularly relevant to exploration of the personal meaning, and possible 'payoffs', of a client's symptom, is Tschudi's (1977) *ABC procedure*.

Measures of Personal Construct Transitions and Processes

Kelly regarded emotions as being associated with transitions in construing, and there have been some attempts to assess emotions from this perspective. For example, Viney (1983) applies content analysis scales to an interview with open-ended instructions to assess anxiety, threat, and various other aspects of the subject's experience. Questionnaire measures of such emotions and of other personal construct processes have also been developed, but require further investigation of their psychometric properties.

Although only partially drawing upon personal construct theory, Toukmanian's (1986) system of *Levels of Client Perceptual Processing* provides a useful method of assessing, for example, from therapy transcripts, the extent to which a person is exploring alternative constructions of events.

FUTURE PERSPECTIVES

While it is likely that repertory grid technique will continue to be a popular and versatile method of assessment of the structure and content of construing, further developments in the field, consistent with those in constructivist psychology more generally (Neimeyer, 1993), are likely increasingly to focus on the analysis of less structured material such as narratives, particularly appropriate for the investigation of processes of construing.

CONCLUSIONS

Personal construct assessment methods allow the subject to be considered from his or her own perspective rather than from that of the observer.

One of their principal characteristics is flexibility: they may be adapted to a very wide range of circumstances, they combine both a qualitative and a quantitative approach, and, although commonly regarded as idiographic, they may also be applied nomothetically.

As well as providing an understanding of an individual's construct system and individualized measures of change in this system, they may also be used as intervention techniques to modify construing. This flexibility is reflected in the breadth of application of these methods, which, as well as the clinical context in which they were originally developed (Winter, 1992), have been used extensively in educational (Denicolo & Pope, 2000), business (Stewart & Stewart, 1981), and other fields in a range of cultural settings.

Personality Assessment (General), Theoretical Perspective: Constructivism, Qualitative Methods, Subjective Methods

PERSONALITY ASSESSMENT (GENERAL)

INTRODUCTION

Personality can be viewed as both a composite of physical, psychological, and social qualities that distinguish persons from one another and as a self-regulatory system endowed with proactive properties that enable individuals to interact actively with the environment and to contribute to the course of their own development. The aim of personality assessment, then, is to identify and to evaluate both the distinctive features of each person as they impress themselves upon others and the self-regulative mechanisms that underlie the functioning of personality as a whole system and contribute to its continuity and coherence over time and across situations. Accomplishing these goals requires a wide variety of assessment procedures and techniques. Further diversity in techniques derives from the existence of different conceptions of personality; different theoretical conceptions highlight diverse phenomena ranging from stable personal tendencies to dynamic, affective, and cognitive processes to the management of self and interpersonal relations. Assessors

thus adopt different personality assessment aims in different assessment contexts and employ multiple criteria to evaluate the quality of measurement.

THE DOMAIN OF PERSONALITY ASSESSMENT

Personality assessment refers to procedures designed to identify and evaluate the enduring psychological qualities, including modes of thinking, feeling and acting, that characterize the person as a self-regulatory system and that distinguish individuals from one another. As such it addresses the cognitive, affective, the moral and volitional component of individual functioning including cognitive abilities and styles, temperament and mood, motives, attitudes and values, habitual behaviours, coping strategies, and self-regulatory mechanisms. Although personality assessment has been often identified with the measurement of quantifiable individual differences, it includes both quantitative and qualitative techniques. Assessment serves both research and practice in its provision of descriptive, predictive, and explanatory information about persons.

Personality assessment plays a critical role in a variety of applied settings in clinical, educational, and organizational psychology, to foster learning and motivation, to prevent and to diagnose psychological suffering, and to promote health and to make the best use of individual potentials. A broader understanding of the basic processes that lie at the basis of individual–environment transactions is made possible by close scrutiny of personality variables (commonly construed as dimensions) that are directly related to those processes.

Contemporary personality assessment is marked by a diversity of assessment methods. Different assessment aims lead investigators to focus on different aspects of individual functioning. Different sources of data and assessment techniques are commonly in use. Some assessors aim to measure overt psychological tendencies, whereas other target internal psychological dynamics. Some focus on the expression and regulation of specific personality dimensions, such as aggression, altruism or emotional intelligence, whereas others focus on sets of behavioural tendencies that might yield a comprehensive description of personality and an understanding of its consistency across space and time. Some employ person-centred strategies that highlight the distinctive patterns of affect, cognition, and behaviour that may recur across individuals or be unique of any individual, whereas others employ variable centred approaches that highlight the influences that specific individual characteristics exert on personality development and adjustment over the course of life and across populations. Many investigators aim to provide global personality assessments – that is, assessments of overall behavioural tendencies averaged together across contexts – whereas others pursue contextualized descriptions that capture the ways in which different people vary their characteristic responses across settings.

In principle, personality assessment should target both the distinctive features of any person as they impress others and prove critical in various situations or performances, and the regulative mechanisms which underlie the functioning of personality as a whole system and which grant continuity and coherence over time and across situations. In practice, the assessment goals one pursues generally determines whether one focuses on the former or the latter, and the nature of the data one relies upon.

The kind of data processed to assess an individual's personality may include life outcomes (L-data), observer ratings (O-data), situational tests (T-data), and self-reports (S-data; Block, 1977; Cattell, 1957). The kind of techniques commonly used include individual and group interviews, questionnaires and adjectives list, situational task, physiological measures, projective test, narratives, and biographies.

Different data and techniques in their turn are hardly amenable under common criteria of reliability and validity. Thus, one may wonder whether there is any congruency and convergency among the various set of data and modes of assessment, even when the target persons are the same.

Indeed, personality assessment is a territory of broad diversities where both openness and cautiousness are needed. On the one hand, one should be ready to use multiple data and techniques to dig into the complexity of

individual experience, on the other hand one should recall that data and techniques do not speak for themselves but always are processed and employed in accord with a theory that dictates their selection and use.

The main reason for the existence of diversity in aims, contents, and methods of personality assessment is the presence, in the contemporary field, of different viewpoints and paradigms about personality itself (Caprara & Cervone, 2000). Different theories of personality have competed in the past and yet guide the assessor's decision about the targets, the data and the techniques.

We sketch in the following paragraphs the main events and issues that have marked the progress of personality assessment as a proper discipline.

THE PAST

In the case of personality assessment, as in other domains of psychological inquiry, one finds a long history of conjectures but only a short history of systematic research. Intuitive assessments of personality undoubtedly predate recorded history, in that personality assessment is an inevitable task of everyday social life. No one can resist evaluating other people with whom one has to deal, and no one can resist trying to manage the impression one forms in others.

Before psychologists, poets gave the public what was already common knowledge.

Homer celebrated the courage and anger of Achilles, the devotion of Hector, and the astuteness of Ulysses long before Theophrastus's description of characters (the liar, the adulterer, etc.) or the establishment of the long lasting Hippocratic-Galenic typology (the sanguine, melancholic, choleric, and phlegmatic types). Psychologists only came later to bring order to matters that everybody already knew through common sense and intuition. They reinvented and systematized evaluation procedures which had long been in use to select soldiers, administrators, and servants, and which were a great part of clinicians' repertoire and wisdom.

As in other fields of psychology, it was not easy to replace the intelligence of tradition and of intuition with procedures that were carrying new instruments, rules, and standards. The enterprise was further made difficult by competitive theories about individual functioning and personality.

EARLIER ESTABLISHMENT OF PERSONALITY ASSESSMENT AS A DOMAIN OF PSYCHOLOGICAL INQUIRY

Modern approaches to personality assessment can be traced to the late 19th and early 20th century efforts to assess intelligence, temperament and vulnerability to mental illness (Ajken, 1996).

Galton (1879) was a convinced advocate of measurement of both intellectual abilities and character, and, along with other methods, he was the first to introduce word association, a technique for assessing personality that Kraepelin (1892) and Jung (1910) applied later in clinical situation.

Early contributions of Binet and Simon (1905) and Heymans and Wiersma (1906–1909) and Spearman (1927) are particularly noteworthy, since each marked the beginning of long traditions of research on the assessment of intelligence and temperament.

The Woodworth Personal Data Sheet, the first instrument explicitly developed to assess personality at a mass level, appeared in 1918 (Woodworth, 1920). The Rorschach Inkblot Test, the most famous projective technique ever produced, appeared in 1920 (Rorschach, 1921).

Two main lines of inquiry set the stage of subsequent developments of personality assessment. One primarily focused on phenotypic inter-individual differences, whereas the other was mostly focused on the internal dynamics of personality. Investigators who assessed phenotypic individual differences conceived personality as an architecture of habits or tendencies. This tradition was only marginally concerned with the internal mechanisms underlying psychological organization and integration of the person into a coherent whole. In contrast, students focusing on personality dynamics aimed to understand how different mental structures develop and operate in concert under the push of internal and external pressures. Along this line of thought Freud's contributions exerted an enormous impact on personality assessment for over half a century, both within and far beyond the

psychoanalytic circles. Indeed Freud, although not using the term personality, was providing a theory of personality development, functioning and change, in contrast to most of the psychology of individual differences, which remained confined to the description of behavioural tendencies (Caprara & Cervone, 2000).

In the 1930s–1940s, personality psychology and personality assessment fully established their autonomous position among the most important sub-fields of psychological inquiry. Stern (1935) and Allport (1937) launched the programme of the new discipline of Personality Psychology, and Murray (1938) decisively reoriented personality assessment towards the whole person.

Murray did not hesitate to bring together ideas from different theoretical viewpoints on personality development and functioning, to generate procedures and instruments capable of tapping the manifold aspects of the whole and capturing the uniqueness of each individual. His most memorable contribution to assessment is his invention of the Thematic Apperception Test (TAT), a technique that is still in use. However, no less important for the subsequent developments of personality assessment was his notion of the diagnostic council, in which many clinicians come together to bring different perspectives on a given client, as well as the assessment programme he directed for the Office of Strategic Offices in which multiple techniques, including interviews, informal observations, individual and group task, and projective techniques, provided the data upon which the diagnostic council had to decide the suitability of candidates for particular assignments.

By the mid-20th century, personality psychology was a well-established domain of psychological inquiry. Yet there was not a unique science of personality, since competing theories were far from reaching a common ground upon which to cumulate their knowledge.

Trait psychology, psycho-dynamic psychology, and social learning were the most influential approaches to personality. Trait psychology largely subsumed the individual differences tradition in conceiving personality as an organization whose building blocks are real 'neuropsychic structures ... with the capacity to render many stimuli functionally equivalent, and to initiate and guide consistent forms of adaptive and expressive behaviour' (Allport, 1937: 295). Psycho-dynamic approaches continued to focus on internal processes and mechanisms such as drives and defences. Social learning further widened the traditional scope of learning theory paving the way to subsequent social cognitive theories focusing on imitation, expectations, and the influence of social situations in shaping behaviours, attitudes and motives.

Obviously, these theoretical diversities fostered significant differences in personality assessment techniques; however, real disputes were mostly confined to academic circles. In practice, divergent viewpoints regarding personality did not prevent multiple 'hybrid' solutions.

Projective techniques like the Rorschach test and TAT were largely endorsed by scientists and practitioners that shared very little of their psycho-dynamic background.

Trait inventories were commonly used, no matter whether the notion of trait the assessor was referring to was conceived as an inherited characteristic, a habitual behaviour, or an institutionally defined descriptor of subjective states or behaviours.

By the middle of the 20th century, personality assessment not only could count upon a large variety of instruments but also a consistent body of knowledge regarding the sources of data and the quality of measures. Progress came from work in psychometrics, including the extension of factor analytic methods to personality. The seminal contributions of Cattell (1946), Cronbach (1949, 1951), and Cronbach and Meehl (1955) on the quality of personality measures and on the various methods to ascertain their validity were long lasting and influential.

CONTEMPORARY TRENDS

Over the second half of the 20th century, the vicissitudes of personality assessment continued to mirror the disputes and progress of personality psychology.

The cognitive revolution returned a focus to the subject as an active interpreter of his or her world and led to examine cognitive competencies and styles, personal constructs, beliefs, and expectancies. Interactionism (Magnusson & Endler, 1977) highlighted individual–environment interactions and thus reoriented the

study of interindividual differences from global dispositions to contextualized behavioural strategies. A new conception of personality as agency capable of making things happen according to its anticipations and standards widened the traditional view of personality as a mediating system, largely operating reactively under the guidance of nature and culture (Bandura, 1986). These changes in personality theorizing inevitably created new assessment aims, such as the assessment of skills and knowledge that underlie overt behavioural competencies, and new procedures, including cognitive techniques to measure individual differences in knowledge accessibility and biopsychological techniques for tapping brain systems in personality functioning. In addition, access to large and diverse populations and computer aided psychometrics further widened the scope of the personality assessment process.

A renewed interest in temperament has promoted the development of new procedures to assess earlier features of personality (emotionality, activity level, attention span) mostly related to the regulation of affects and action. Studies on emotional, social and practical intelligence have brought closer traditions of research on intelligence and personality that had often developed along separate pathways, the former focusing on cognitive abilities and problem solving and the latter on interpersonal relations and social behaviours. Work on emotional intelligence revealed the need for new measures to tap aspects of intelligence not covered by traditional IQ scales.

The past decade has witnessed much progress in understanding the cognitive unconscious – that is, informational and motivational processes that operate beyond individual awareness – and in a manner that has little in common with the psychoanalytic unconscious. Measures of implicit cognitiveness, though still in their early stages of development, promise significantly to supplement traditional explicit self-report measures.

Finally, the self-system is a new territory for personality assessment. Here, the goal is to assess the agentic properties of personality, namely the cognitive and motivational structures that lie at the basis of any behavioural dispositions and grant their coherence, distinctiveness, and effectiveness. These lead to a focus on self-representations, self-beliefs, and self-regulatory mechanisms as they operate in concert in specific contexts and across settings. All this implies a revision of traditional constructs of personality psychology as well as of the variables targeted by personality assessment.

This progress cannot be disjoined from the great progress of neurosciences in advancing our knowledge of gene–environment interplay and brain functioning as well as from the technological devices that allow the biological mechanisms underlying thought, affect, and action to be measured. In addition to traditional biosignal measures (HR, EEG, etc.) one can only guess the promise of DNA analysis and of brain imaging for personality assessment.

FUTURE PERSPECTIVES

Throughout much of its history, a great part of personality psychology has been concerned with individual differences in observable variations in styles of behaviour, affect, and cognition. The variations have been organized according to, and traced back to, simple systems of dispositional constructs. Trait constructs have been posited to account for stable patterns of experience and action that people exhibit, and that distinguish them from one another across times and situations. Within this line of thinking, personality has been conceptualized as a hierarchical organization with high-level traits (e.g. extroversion) that organize lower level tendencies (e.g. sociability) which, in turn, supervise lower level behavioural habits (e.g. talkative) (Eysenck, 1970).

A key question here is to identify the number and nature of the high-level traits. In the past, alternative taxonomies competed. Today, a broad consensus has emerged. It centres on five global dispositional tendencies (the so called Big Five): Extroversion, Agreeableness, Conscientiousness, Emotional Stability, and Openness to experience. A variety of self-report and observer-report measures have been produced to assess the five dispositions as well as a variety of other traits that correspond to their different facets of each main trait or the result of their combinations from them and from their combinations. Among the most diffused instruments one finds the NEOPI-R of Costa and McCrae (1992) and

the BFQ of Caprara, Barbaranelli, Borgogni and Perugini (1993).

This approach, however, meets only part of what personality assessment should aim to achieve.

The Five Factor Model (FFM) offers a highly convenient lexicon to help subject–assessor communication. The clarity of the conceptualization of the five factors may increase raters' reliability and reduce interrater variability across settings and times. Its concurrent and predictive validity in educational and organizational settings, as well as in health and adjustment, is well documented (John & Srivastava, 1999; McCrae & Costa, 1999). However, FFM does not go very far beyond description and prediction at the level of surface behavioural tendencies. In reality, it is beyond its reach to explain the underlying mechanisms which govern behaviour and grant its continuity and coherence and it does not say anything about the essential characteristics of being a person, namely self-awareness and intentionality.

Whereas self-report and observer ratings remain the main methods, and habitual behaviours the primary sources of data, of personality assessment, one wonders whether any access is possible to feelings, beliefs and preferences in absence of a theory of the person as a self-reflecting agent.

In this regard, psycho-dynamic theories have been much more sensitive and concerned with the complexity of individual experience. But the Freudian metapsychology, namely its theory of mind, all constructed on the vicissitudes of drives, ultimately collapsed. Looking at recent trends in psychoanalysis, it is quite uncertain whether new object relationships or interpersonal approaches will provide a new body of knowledge regarding development and functioning of personality able to reconcile psychoanalysis with psychology (Caprara & Cervone, 2000). Psychoanalytic scientists and clinicians continue to use interviews and projective techniques but their validity remain questionable as they are hardly amenable to the standard criteria which guide psychological measurement (Lilienfeld, Wood & Garb, 2000).

To find an alternative to psycho-dynamic approaches, able to meet the demands that trait psychology seems incapable to address, one should turn to social cognitive theory.

In conceiving of personality as an open, dynamic, unifying and integrating system, social cognitive theorists (Bandura, 1986, 2001; Caprara & Cervone, 2000) point to the emerging properties of the mind and focus on the processes and mechanisms conducive to knowledge structures which enable personality to function as a proactive self-regulatory system. They do not argue whether people have personal dispositions, nor their determinative role in personality functioning, but rather how dispositions are conceptualized and operationalized. Dispositions may correspond to habitual styles of behaviour rooted in genotypes, or to self-regulatory structures (as internal standards, values, and goals, efficacy and control beliefs, appraisals and outcome expectancies, coping and self-serving mechanisms) resulting from the organization of affect, cognition and behaviour. They claim that self-regulatory structures guide habitual behaviours. Thus, they focus on the construction of personality as an integrative and coherent system as it takes place over the course of life, on the processes which enable the system to function proactively with the environment, and on the self-structures which orchestrate these processes. Where assessment issues come to the fore, the primary targets are self-regulatory structures like self-representations, self-efficacy beliefs, personal goals and standards, as self-reflective and self-directive processes enable individuals to meet environmental opportunities and constraints as well as to maintain personally valued courses of action. Social-cognitive theorists also stress the persons must be assessed with respect to their life contexts. People's self-regulatory abilities enable them to vary their behaviour strategically in accord with the perceived opportunities and demands of environmental settings. One must tap these contextual variations to assess fully the distinctive features of an individual's personality (Cervone, Shadel & Jencius, 2001).

CONCLUSIONS

In general, the contemporary field of personality assessment can be characterized as one that features an increasing sophistication in assessment methods to tap manifold aspects of individuality including and beyond traits. While focusing on personality functioning across

settings and over the entire course of life requires multiple techniques able to meet basic psychometric standards, new technologies carry extraordinary opportunities to collect and to process enormous amounts of data, to monitor ongoing thoughts, feelings, behaviours, and their biological correlates. Progress, however, has not yet led to a uniform set of assessment methods, but to a diverse array of practices that each sheds light on the nature of individuals and individual differences. Both opportunities and diversities underscore the importance of robust theories able to integrate and guide methods and techniques within a unified science of personality.

Personality Assessment through Longitudinal Designs

PERSONALITY ASSESSMENT THROUGH LONGITUDINAL DESIGNS

INTRODUCTION

Personality research is concerned with individual differences on the one hand and with the total person on the other (see Pervin & John, 2001). Of course, people are similar in some ways; however, they differ from one another in several aspects. The complex relationships between those aspects make the person(ality) as a whole functioning. But, how can one define personality in a more concrete way? Pervin and John answer this question: 'Personality represents those characteristics of the person that account for consistent patterns of behaviour.' Of course, other definitions are given as well, and dozens of them may be known to the reader. These definitions are more or less useful in focusing on different fields of scientific research of personality, such as organization and dynamics of personality domains, structure and process, traits and states, action and situation, environment and genetics, etc.

The study of individuals from a personality theoretical perspective should answer questions regarding: *What* they are like, *how* they became that way, and *why* they behave as they do. The generic aspects behind these questions can be described by the underlying (meta-)theoretical constructs: structure (what), process (why), and growth and development (how). Theories of personality can be compared in terms of the constructs, tools, instruments, and empirical research designs which they use to determine the what, why, and how of personality.

Structure

The concept *structure* (what) refers to the more stable and enduring aspects of personality. Such structural concepts as *response*, *habit*, *trait*, and *type* have been popular in efforts to conceptualize what people are like. The concept of trait refers to the consistency of individual reponse to a variety of situations and focuses on inter-individual differences and stability (of these interindividual differences). Another related question focuses on the organization of the structural units, e.g. in a hierarchy of these units and inter- and intraindividual stability of the organizational structure.

Process

The concept of *process* (why) refers to the dynamic motivational aspects and constructs which are considered to account for behaviour, e.g. in a large family of personality theories the organism is viewed as seeking a state of balance, homeostasis, or equilibrium.

Growth and Development

Growth and development (how) are related to the concept of structure and process, not only in terms of changes in structure and processes from infancy to maturity, but also – and this is a domain of increasing interest – from maturity to middle age and even to old age.

Again, growth and development are characterized by individual differences, up to the extreme of psychopathological behaviour: why are some people capable of coping with the stress of daily life and generally show high-level life-satisfaction, whereas others develop abnormal responses? Personality theory should suggest intervention strategies by which behaviour could be modified. Empirical research strategies should enable the researcher to differentiate stability and invariance from change in a reliable and valid way.

So, according to Pervin and John (2001), a complete theory of personality must take into account structure, process, development, psychopathology, and change.

The term development refers not only to those processes that are biologically programmed and inherent in the organism, but also to those in which the organism is irreversibly changed or transformed by interaction with the environment.

As the result of one's life history with its accumulating record of adaptations both to biological and to social events, there is a continually changing basis within the individual for perceiving and responding to new events. According to Thomae (1970) personality can be defined as the essence of all events, which unite into an individual biography. From this perspective, development might be described as the individual history of life. Personality development, then, is conceptualized as a reflection of the attempts by the individual to maintain a sense of continuity. Striving for continuity is characterized by the subjective experience of the person's own development. In recent years, two broad classes of methodological techniques, referred to as person-centred methods, have been introduced in response to this challenge: bottom-up and top-down strategies. The bottom-up strategies begin with idiosyncratic individual histories, and the analytical steps identify important commonalities and differences across lives, leading to aggregation of histories into relatively homogeneous groups. The top-down strategies begin with coarse-grained descriptions of heterogeneous – in terms of details of live histories – populations and partition them into progressively more homogeneous subgroups, each of which is described using information over time from multiple life domains. Developmental researchers are increasingly interested in the use of such person-centred methods. Thus, the aim of the investigation of development in middle and old age is not to discover universals, not to make predictions that will hold good over time, and certainly not to control, but, instead, to explicate contexts and thereby to achieve new insights and new understanding.

Development and change are growth driven by environmental determinants (such as culture, social class, family) and by genetic determinants (e.g. differences in temperament), and by interactions of influences from both domains.

These different determinants are illustrated in a taxonomy of traits presented by Schaie (1996). *Biostable traits* represent a class of behaviours that may be genetically determined or constrained by environmental influences that occur early in life, perhaps during a critical imprinting period. These traits typically show systematic gender differences at all age levels, but are rather stable across age, whether examined in cross-sectional or longitudinal data. *Acculturated traits*, conversely, appear to be overdetermined by environmental events occurring at different life stages and tend to be subjected to rather rapid modification by sociocultural change. These traits usually display no systematic gender differences. Their age differences rarely form systematic patterns and can usually be resolved into generational shifts and/or secular trend components upon sequential analysis. *Biocultural traits* display ontogenetic trends whose expression is modified either by generational shifts or by sociocultural events that affect all age levels in a similar fashion. Cross-sectional data for such traits would typically show age × gender interactions.

COMPARABILITY OF CONSTRUCTS

Particularly, studies of personality in adulthood and ageing continue to be dominated by the question of whether personality changes with time and/or ageing or whether it is stable (see Ryff, Kwan & Singer, 2001, for the most recent review).

Early formulations of development, from Jung, Erikson, Bühler, and later, Neugarten, and still later, Levinson, Bould, Vaillant, and Loevinger (for a review see Wrightsman, 1994), illustrate the idea that personality was dynamic and evolving through time. As Costa and McCrae rightly argued, these perspectives needed rigorous empirical testing and validation, and not just enthusiastic endorsement. Drawing on factor analytically derived models, they amassed extensive evidence in support of personality stability in five major dimensions of personality: neuroticism, extraversion, openness, agreeableness, and conscientiousness (Costa & McCrae, 1988). Their findings were based on longitudinal and cross-sectional analyses, self and other reports (e.g. spouse), and included detailed evaluations of whether the obtained effects were best interpreted as due to age, period, or cohort effects.

Of course, personality, personality structures, and personality development have many different aspects, and can be approached from many different (meta-theoretical) angles: trait-perspective on the one hand, self-identity and self, meaning of life, future time perspective, control

beliefs; well-being, affects, quality of life; stress and coping, goals, projects and life tasks on the other hand.

Thus, links between personality (in terms of traits) and constructs such as well-being are of growing interest (see Schmutte & Ryff, 1997). Traits such as neuroticism have been used to predict negative affect and depressive symptoms (e.g. McCrae & Costa, 1990). These queries are fraught with problems of both construct and source overlap (i.e. negative affect is part of what defines neuroticism, and both are typically measured via self-report from the same respondent). High levels of variance explained are likely fuelled by internal tautologies.

Such problems demand greater attention by personality researchers. The difficulties can be partially adressed by careful evaluation of theoretical starting points and measurement instruments as well as use of diverse methods (e.g. self-reports, spousal reports, behavioural observations). At a more general level, however, there is a need for caution, regarding the reification of constructs (traits, well-being, coping, goals, the self), all of which likely share overlapping space in the parsing of differences between individuals. Extending personality research beyond its own confines (i.e. connecting individual-difference variables to other disciplines and domains) is another response to the problem of construct redundancy.

The general problem adressed in every case is that of comparability of personality dimensions and comparability of constructs across cultures, groups, situations, and times of measurement (Rudinger & Rietz, 1999).

This comparability includes measurement and conceptual equivalence, the framework of these just mentioned contexts. Measurement comparability (i.e. equivalence, of instruments or even items) and conceptual comparability (i.e. equivalence of the theoretical constructs) have to be distinguished very carefully.

In life-span oriented research the same theoretical variables are compared, but not necessarily the same instruments, i.e. not necessarily the same items. Probably, one has to formulate items quite differently in different cohorts or measurement points in order to mirror the same construct, facts we know from developmental research across age, e.g. in the field of cognitive functioning or attachment research.

There are at least three levels of inference from empirical measures to constructs (Van de Vijver, 1995):

- macro or domain constructs (e.g. personality, intelligence, social relations),
- instruments (e.g. personality questionnaires, intelligence tests, social relations scales), and
- single items and one-dimensional simple measures (e.g. statements in questionnaires, tapping speed, intelligence test items).

For instance, to clarify this very important issue, often one cannot use the same instrument for measuring quality of life across ages, but one can ask what is important for the subjects of different ages at different points in time and different countries or cultures regarding quality of life. By this procedure one can investigate what each macro-construct means within different contexts. The only non-trivial premise is that concepts used (e.g. quality of life) are present in different contexts with similar semantics. Consequently, one has to rely on idiographical as well as on nomothetical definitions of macro constructs.

These theoretical problems cannot be solved in a satisfying manner by application of statistical models, since measurement comparability and conceptual equivalence are confounded.

METHODOLOGICAL ISSUES

In the field of personality one can focus on methodological priorities. For example, the question of whether personality changes or is stable across adult life was accompanied by extensive attention to issues of research design (cross-sectional, longitudinal, sequential), assessment tools (clinical interviews, projective tests, structured self-report procedures), and strategies of data analysis (structural invariance, correlational and mean-level change).

Design

Focusing on development, growth and change implies that the character of studies of personality has to be time-oriented, i.e. longitudinal.

Although longitudinal research designs can take over on very different shapes, they share the feature that the data describe what happened

to the research units during a series of time points. That is, data are collected for the same set of research units for (but not necessarily) two or more occasions, in principle allowing for intra-individual comparisons across time. In contrast, cross-sectional data refer to the situation at one particular point in time.

The participants in a typical longitudinal study are asked to provide information about their behaviour and attitudes regarding the issues of interest at a number of separate occasions in time (also called the 'phases' or 'waves' of the study).

One distinct disadvantage of every type of prospective longitudinal study (such as the time series, panel, or the intervention study) is that across-time analyses can only be conducted after at least two waves of data collection have been completed.

However, longitudinal data may be collected in a single-wave-study, by asking questions on what happened in the past (so-called retrospective questions) – quite often exercised in personality research. Inclusion of retrospective questions in a questionnaire or interview or exploration would seem a quick and easy way to collect information about what happened to the participants in the past. This information has to be checked carefully, since the quality of answers might suffer from desirability of the respondent, or might reflect the re-appraisal of the past dependent on the present situations, or might be influenced by the tendency to exhibit continuity of life-history. Although such data are collected at the same occasion, they may cover an extended period of time. To define 'longitudinal' and 'repeated measures' synonymously is to confuse the design of a particular study with the form of the data one wishes to obtain. However, the majority of studies belong to the repeated measures type and, consequently, statistical methodology applied in longitudinal research has its focus in repeated measurement problems.

The longitudinal approach in general offers unique opportunities to investigate determinants and characteristics of transitional processes (e.g. Hartelsman, van der Maas & Molenaar, 1998), interindividual differences and/in intraindividual change (Nesselroade & Featherman, 1997), as well as changes in structure and structures of change (McArdle & Nesselroade, 1994). Longitudinal designs offer not only many advantages, but also suffer from drawbacks as selection effects, systematic attrition and different types of selectivity (Bosworth & Schaie, 1999), and from incomplete data sets related to these processes (McArdle & Hamagami, 1991).

Observed Variables and Latent Constructs

Behavioural scientists who investigate phenomena in areas such as personality and motivation are rarely interested in their subject's response to specific items or in the summary scores obtained on a particular measurement scale. Instead, such responses are treated as one of many possible indicators of the respondent's location to an unobservable, theoretically defined, or empirically abstracted scientific construct.

Although we must measure the observable phenotype or surface trait, it is usually the unobserved (latent) genotype or source trait that is the object of inquiry for the definition of stability and (developmental) change.

A variety of techniques are, of course, available under the rubrics of scaling, linear structural equation and factor analysis methods that are suitable to examine the relationship between the observed behaviours and the underlying latent constructs.

Stability and Reliability

The conceptual distinction between stability and reliability has a central role and long history in longitudinal and personality research. Separation of reliability and stability is limited to covariances and correlations, ignoring the mean. In terms of Structural Equation Modelling (SEM) the definition of reliability refers to the assumptions about relations of theoretical concepts to a set of measured variables. Reliability describes the quality or measurement of the phenomena under study. The definition of stability refers to the structural model, specifying the relations hypothesized within a set of theoretical concepts, i.e. latent variables. Stability in this sense mirrors the consistency of interindividual differences in the domain of latent constructs and refers to theoretical assumptions about the time bound process. Stability does not exclude interindividual

differences in intraindividual change at the observed or latent level.

This question is part of the 'trait–state' debate (Usala & Hertzog, 1991). A state-theoretical assumption about the relational system under study can be modelled by Confirmatory Factor Analyses (CFA) models with time correlated factors or by autoregressive models. Since the classical definition of trait and state contains a time bound component (Cattell, 1950), CFA-type models do not seem optimal to disentangle trait and state variance, since the sequentiality of time, the essential feature of a longitudinal data set, is lost.

In the domain of traits, longitudinal age patterns on personality variables are generally quite stable. This has been demonstrated by Schaie (1996) in his Seattle Longitudinal Study (SLS) which did not address the study of personality per se, but he collected a substantial corpus of data on adult development of personality across a large time span and many cohorts. Schaie (1996) came to the following conclusion: 'Significant cross-sectional age-differences were found for all personality factors. However, these differences can largely be explained by a pattern of positive and negative cohort differences. Far fewer significant within-subject changes were found. Most noteworthy were modest within-subject decreases with age in Superego Strength and Threctia (threat reactivity) and a dramatic decline in Honesty. Affectothymia decreases from young adulthood to middle age but increases significantly into old age. Both Community Involvement and Political Concern increase with age.'

Structural Equivalence and Measurement Equivalence

One topic frequently addressed by longitudinal research particularly in the field of personality involves assessment of invariance of constructs over time (Horn & McArdle, 1992; Rietz, 1996). From the traditional perspective the invariance definition of constructs over time is synonymous with definitions of factorial invariance. This involves the same relative magnitude of factor, loadings of variables on factors (measurement equivalence) as well as the same degree of relations between the factors (structural equivalence). The degree of relation between (oblique) factors can range from zero to one in correlational terms. The emergence of qualitatively new structures can be mirrored by relations between factors changing from measurement point to measurement point. Differentiation can be indicated by weaker and weaker relations across time, and dedifferentiation by increasing relations across time. If the relations become perfect, the factors collapse to one factor. Two types of invariance need to be considered: (1) invariance across multiple groups of subpopulations, such as those usually found in cross-sectional studies, and (2) invariance across time for the same individuals measured longitudinally. Structural equation models can be specified that are suitable for statistical tests of the invariance assumption.

Only when factorial invariance has been demonstrated can one assume that quantitative comparisons of differences in developmental trajectories truly reflect changes in the underlying construct.

FUTURE PERSPECTIVES AND CONCLUSIONS

After decades of research, based on studies of increasing sophistication in design, assessment procedures, sample selection, and data analyses, it turns out: personality in adulthood and later life is characterized by stability and change. What is increasingly clear, however, is that there is considerable variation in how much change (or stability) occurs and for whom.

Whether one finds evidence of personality change or stability is driven powerfully by how one conceptualizes personality and how one measures change. Cumulative evidence, based on psychometrically sound assessment procedures and longitudinal or sequential designs, clearly documents stability and continuity in personality, at the same time that it provides unequivocal support for change and discontinuity. Thus, rather than seek categorical either–or answers to whether personality is stable or changing, Helson (1993) offered a variety of ingenious tools, both in collecting and analysing data and in working creatively across samples and designs to advance understanding of all these realities. The scientific challenge has matured to one of using well-crafted longitudinal studies to discern the full range of change and stability processes and, more importantly, to

understand why they occur, since it is possible that individuals show stability in traits and change in developmental characteristics.

Personality research reveals an emergent shift towards more process-oriented studies. That is, studies of whether traits, well-being, coping strategies, goals, or the self-concept change across time are increasingly replaced with studies that attempt to formulate and to test how particular individual-difference variables work together to account for different outcomes. For example, many investigators use coping strategies or goal orientation to predict variations in well-being. In fact, personality researchers frequently document that individual-difference variables matter through demonstrating their capacity to predict (cross-sectionally) or account for changes (longitudinally) in various aspects of psychological well-being, life satisfaction, or positive affect. Other personality variables, particularly those coming from theories of self and intentional action (e.g. social comparison processes, reflected appraisals, goal orientations), are increasingly investigated as factors that mediate, or moderate, the impact of life challenges or losses on well-being and health.

Linking individual differences to macrolevel structural factors and to internal biological processes will require innovative analytical approaches. The basic challenge is how to use longitudinal data across different domains to represent whole lives, aggregating them into meaningful taxonomies that facilitate how given outcomes come about.

Personality Assessment (General), Intelligence Assessment Through Cohort and Time

PERSONNEL SELECTION, ASSESSMENT IN

INTRODUCTION

In personnel selection, the decision-maker's task is to predict which job applicants are most likely to perform their jobs well, to fit the organization or the workgroup, or occasionally, to remain on the job after being hired. Decisions are often made on the basis of general impressions, unstructured interviews, or other assessments of doubtful validity. There are, however, a number of methods of structured assessment that have been extensively validated and that are generally regarded as fair and cost-effective. These are described below.

ASSESSMENT METHODS

Five types of tests and structured assessments are widely used in personnel selection and evaluation: (1) assessments of experience and background, (2) structured interviews, (3) standardized tests, (4) simulations and work samples, and (5) assessment centres. Each is discussed below.

Assessments of Biographical Information

More than fifty years of research documents strong and systematic links between the information presented on application blanks and resumés ('biodata') and future job performance and success. This research describes two different empirically based strategies for using biodata in selection: (1) the development of empirical keys, or data-based systems, and (2) the classification of applicants into homogeneous groups based on biographical information. Biodata inventories developed according to these methods are consistently identified as among the most valid and cost-effective methods of assessment for personnel selection (Stokes, Mumford & Owens, 1994). More recent research has moved in the direction of theories that classify persons on the basis of their patterns of past behaviour and that predict future performance based on those classifications.

Structured Interviews

Nearly all employers use interviews as part of their selection systems, but this technique was long held in disrepute by the research community. From the 1940s to the 1980s, research on the reliability and validity of the employment interview portrayed a consistently negative picture (Arvey & Campion, 1982). The correlations between interview ratings and measures of performance or success rarely exceeded the teens and were often embarrassingly close to zero.

More recent research suggests that interviews can indeed be a valid method of selecting employees, as long as structure is imposed (McDaniel, Whetzel, Schmidt & Maurer, 1994). Campion, Palmer and Campion (1997) review the effects of fifteen possible components of structure (e.g. multiple interviewers, scripted questions, answer guides) and conclude that all methods of adding structure seem to help, but there is no professional consensus about which methods of structuring interviews are best or worst.

One interview format, referred to as a 'situational interview', asks examinees to describe how they would behave in several hypothetical but critical situations. Responses are independently rated by multiple interviewers, and composite ratings are used to make decisions about examinees. An alternative is to structure interviews around discussions of past behaviour on the job. Rather than asking what a person might do in a hypothetical situation, interviewers ask what he or she did do in specific situations encountered in previous jobs. McDaniel et al.'s (1994) review suggests that both show higher levels of validity than unstructured interviews, and that situational interviews work best.

Standardized Tests

Written and computer-administered tests of abilities, skills, and personality characteristics are extensively used in personnel assessment, and have been the focus of a substantially large body of research (Schmidt & Hunter, 1999). The use of written tests is much more common for office positions than for production and sales jobs (the *Minnesota Clerical Test* is an exemplar of this class of tests). Written tests are widely used for selection and placement in the federal, state, county, and local governments, and are very common in the military. The *Armed Service Vocational Aptitude Test* is administered to over one million examinees each year, making the Armed Services possibly the single largest consumer of tests and structured assessment methods in the world.

Research in personnel selection has focused most heavily on tests of cognitive ability. Scores on standardized tests of cognitive ability are related to measures of performance and success in virtually every job studied (Schmidt & Hunter, 1999). Compared with other methods of assessment, cognitive ability tests are relatively inexpensive, easy to obtain, have an extensive record of validity, and need not be time-consuming (e.g. the *Wonderlic Personnel Test* can be administered in 12 minutes and scored in seconds). However, there are some features of cognitive ability tests that can limit their attractiveness to organizations. Most important, average scores on cognitive ability tests are likely to vary as a function of race and ethnicity (Neisser et al., 1996). The causes and the meaning of differences in average test scores across groups have been among the most widely researched and contentious issues in the field of psychological testing, with no ready resolutions in sight.

The use of personality inventories as predictors of job performance has been a subject of controversy for nearly 30 years. As a result of several recent reviews of research on personality inventories (Barrick & Mount, 1991; Hough, Eaton, Dunnette, Kamp & McCloy, 1990), there is increasing optimism about their potential usefulness. In particular, there is evidence that measures of agreeableness, conscientiousness, and openness to experience are related to performance in a wide range of jobs. Average validities for measures of these traits are typically lower than those demonstrated by cognitive ability tests, but the evidence does suggest that specific, well-chosen personality inventories can make a worthwhile contribution to predicting who will succeed or fail on the job.

One potential drawback to the use of personality inventories is that many are susceptible to faking (e.g. applicants may distort their responses to appear more dependable or agreeable than they really are). Research on the effects of response distortion suggests that it does not substantially affect the validity of personality inventories as predictors of performance (Hough et al., 1990), but that it can have an influence on which candidates are accepted or rejected.

A potentially more serious drawback to the use of personality tests in hiring is that some of the most popular and widely used tests (e.g. *Myers–Briggs Type Indicator*) have little proven validity and utility. Similarly, projective tests (e.g. the *Rorschach Inkblot Test*) or tests of psychopathology (e.g. *The Minnesota Multiphasic Personality Inventory*) are sometimes used in industry, despite decades of research questioning their validity and usefulness.

There are a number of tests designed to assess integrity, dependability, honesty, etc. (O'Bannon, Goldinger & Appleby, 1989). Although early research on these tests was discouraging, there is now clear evidence that integrity tests have acceptable levels of validity for predicting a variety of organizationally relevant criteria (Ones, Viswesvaran & Schmidt, 1993).

Work Samples and Simulations

It has long been argued that predictions of future behaviour that are based on samples of the

present behaviour are likely to be more accurate than predictions that are based on measures of specific skills, ability, or knowledge. Work-sample tests that are used in personnel selection range from those that involve relative simple tasks to those involving complex samples of performance. There are two common features to all work-sample tests that should be examined in evaluating these tests. First, every work-sample test puts the applicant in a situation that is similar to a work situation and measures performance on tasks similar to those that make up the job itself. Second, every work sample differs in important ways from the job in which it will be used. Even when the tasks are identical to those required on the job, one might expect that examinees trying to impress their prospective employers will show higher levels of motivation in work-sample tests than they will on the job. Thus, one should regard a work sample as a measure of maximal performance rather than typical performance. This is an important distinction, because measures of maximal performance are not necessarily correlated with measures of typical performance.

Assessment Centres

The term 'assessment centre' refers to a structured combination of assessment techniques that are used to provide a wide-ranging, holistic assessment of each participant. Although the assessment centres used in different organizations differ widely in terms of content and organization, there are several features that nearly all assessment centres share in common and that are distinctive to this approach (Bray, Campbell & Grant, 1974). They include: (a) assessment in groups – small groups of participants are assessed simultaneously, (b) assessment by groups – each participant's behaviour is observed and evaluated by a number of different assessors (e.g. managers, psychologists, consultants, etc.), (c) the use of multiple methods – activities might include ability tests, personality tests, situational tests, interviews, peer evaluations, and performance tests, (d) the use of situational tests – nearly every assessment centre uses some type of work-sample or situational test, although they may vary across organizations, and (e) assessment along multiple dimensions – the final rating is a consensus rating along each of several dimensions.

Empirical evaluations of assessment centres have generally been favourable (Thornton, 1992). Assessment centre ratings have been shown to provide valid predictions of future performance, even when there is a long lag between the assessment centre and the subsequent evaluation of employee performance and success. The major drawback of this method is its practicality for screening large numbers of candidates. Assessment centre methods can be very time-consuming and labour-intensive. Time and money are required to develop assessment exercises, train assessors, administer and score the assessments, etc., and this method does not allow one to make quick decisions about a large number of candidates.

EVALUATING ASSESSMENT METHODS

There have been literally thousands of studies examining the relationship between scores on tests, interviews, and other methods of assessment and measures of job performance, work effectiveness, and additional organizationally relevant criteria (e.g. awards, patents, turnover). Reilly and Chao (1982) examined research on alternatives to standard ability tests and focused on eight alternative methods of predicting future job performance: biodata, interviews, peer evaluations, self-assessments, reference checks, academic performance, expert judgements, and objective tests. They evaluated each technique for its criterion-related validity, practicality, and likelihood of providing unbiased predictions of future performance. Their review suggests that only biodata and peer evaluations show levels of validity that are comparable to the validity of paper-and-pencil tests. They also suggest that none of the alternatives show comparable levels of validity with less adverse impact against minority applicants than standardized cognitive ability tests. A report by the National Academy of Sciences (Wigdor & Garner, 1982) reached a similar conclusion, that in employment testing there are no known alternatives to standard ability tests that are equally informative, equally fair, and of equal technical merit. Hunter and Hunter (1984) reached similar conclusions.

Schmidt and Hunter (1999) summarize the practical and theoretical implications of 85 years

Table 1. Estimates of the validity of widely used tests and assessments (Schmidt & Hunter, 1999)

	Job Performance	Performance in Training
Cognitive Ability Tests	0.51[a]	0.56
Work Samples	0.54	–[b]
Integrity Tests	0.41	0.38
Conscientiousness Measures	0.31	0.30
Structured Interviews	0.51	0.35 (combined structured/ unstructured)
Assessment Centres	0.37	–
Reference Checks	0.26	0.23
Job Experience (years)	0.18	0.01
Years of Education	0.10	0.20
Graphology	0.02	–

[a]The results presented here represent the average correlation between scores on tests, work samples, etc., and measures of job performance and performance in training.
[b]Too few studies of the validity of work samples, assessment centres and graphology as predictors of training performance exist to provide credible estimates of these validities.

of research on the validity and utility of selection tests. Their meta-analysis examines the validity of 19 selection procedures for predicting job performance and training. Table 1 summarizes some of their key findings.

The figures shown in Table 1 include a number of statistical and psychometric corrections that are controversial (Hartigan & Wigdor, 1989), and that probably lead to inflated estimates. For example, estimates of the validity of cognitive ability tests that use more conservative corrections suggest that the correlation between scores on these tests and measures of job performance are probably in the 0.35–0.40 range rather than the 0.51 cited in this table (see Hartigan & Wigdor, 1989). Nevertheless, there does seem to be clear and compelling evidence that selection tests can show substantial validity as predictors of performance, and conclusions about the relative validity of these tests (e.g. ability tests show similar levels of validity to situational interviews) appear reasonable.

Surveys of personnel managers (e.g. Ahlburg, 1992) reveal two depressing findings. First, personnel and human resource professionals are often unaware of the most basic findings of research on the validity of various personnel assessment and selection methods. For example, personnel managers in several countries, including the United States, consistently rank cognitive ability tests as among the least valid and useful tools for selection, and they rank interviews as among the most valid and useful tools for selection. The available body of research, which includes thousands of studies conducted in a wide variety of settings, shows that the opposite is true. Second, even those individuals who know which techniques have been shown to have the most or the least validity are more likely to use techniques such as the interview or assessments of experience. It appears that personnel managers' habit of using less valid methods is a difficult one to break.

CONCLUSIONS

A wide range of valid methods for selecting among job applicants is available, and as technology develops (e.g. advances in computerized testing, video-based simulations), it is likely that many of these methods will continue to improve. Unfortunately, there is a substantial gap between the science of selection testing and typical practice in organizations. The largest single challenge in this area is to convince decision-makers to take advantage of structured assessments in making selection decisions. Murphy and Bartram (in press) note that actual selection decisions are rarely based on individual test scores, and that the processes used in organizations to select workers are often poorly documented and poorly executed. Valid selection methods are readily available, but selection decisions are still usually made, in part or in full, on the basis of unstructured, poorly validated methods of assessment.

PHYSICAL ABILITIES IN WORK SETTINGS

INTRODUCTION

Human physical performance is a domain of human abilities. Many of the assessment problems in this area are those met by psychologists interested in individual differences in other domains of human abilities. However, until recently, the constructs for describing the domain of physical abilities were not well defined and the range of capacities and measures to be included needed to be specified. This entry deals with research on the definition and organization

of physical abilities, the identification of diagnostic and reliable measures for assessing particular physical abilities, and the assessment and predication of performance in physically demanding tasks and jobs.

There is today particular interest in physical abilities in the workplace due to a number of national and social concerns. One concern stems from the increasing number of women seeking entry into physically demanding work. Women are becoming fire fighters, police officers, soldiers, pilots, construction workers, telephone linemen, warehouse loaders, and are entering other jobs formerly occupied only by men. In the US, it is legally mandatory for employers to demonstrate that they are following procedures that are fair to various members of the labour force – men, women, and different minority and ethnic groups. Such developments increase the need to identify the particular physical abilities required for such jobs and to identify objective, reliable, and valid methods for assessing the relevant abilities in applicants for these jobs.

IDENTIFICATION OF PHYSICAL ABILITIES AND MEASURES

Research in this area grew out of research on the dimensions of psychomotor abilities. Over the years, an extensive series of interlocking, experimental, factor-analytic studies attempted to isolate and identify the common variance in a wide range of psychomotor performances. Subsequent studies tended to introduce task variations aimed at sharpening or limiting our ability-factor definitions (for a review see Fleishman, 1972b). It was established that the psychomotor abilities identified (e.g. control precision, rate control, multi-limb coordination, reaction time, finger and manual dexterity, arm–hand steadiness) have little relation to performance of physical tasks and are independent of abilities in the physical performance domain (e.g. Hempel & Fleishman, 1955).

Physical abilities involve larger muscle groups than do psychomotor abilities and require more gross bodily movements. There had been many questions regarding the different basic physical ability dimensions to be assessed, their definitions, and the basic measures most diagnostic of these abilities. Is there a general strength factor? Are ability factors common to muscle groups? Or to movements involving extensor or flexor muscles? Can prolonged strain introduce new physical ability factors? How do conditions of administration (e.g. timed vs. untimed) affect what is measured? Are terms such as agility, speed, strength, and muscular endurance useful, or are they too general?

Fleishman (1964, 1975) described a programme of large-scale factor-analytic studies examining the interrelationships among actual physical performances. These studies involved large batteries of physical performance tests, specifically designed to test various hypotheses about the organization and nature of physical abilities. These studies identified and defined nine physical performance abilities. A recent large-scale study confirmed these findings for both men and women and with a more diverse set of physical tests (see Myers, Gebhardt, Crump & Fleishman, 1993). This programme indicated the range of performances that involved these abilities, provided detailed definitions of each ability, and identified the tests that were reliable and diagnostic of each of them (see also Fleishman & Reilly, 1992).

Definitions of these are provided below:

Static strength: Maximum force that can be exerted against external objects, including lifting, carrying, or pushing heavy objects.

Dynamic strength: Muscular endurance in exerting force continuously or repeatedly and includes power of the muscles to support or move one's body over time.

Explosive strength: Ability to mobilize energy effectively for bursts of muscular effort.

Trunk strength: A limited dynamic strength ability specific to trunk muscles.

Extent flexibility: Ability to flex or stretch trunk and back muscles.

Dynamic flexibility: Ability to make repeated, rapid, flexing trunk movements, involving resilience of the muscles in recovering from strain.

Gross body coordination: Ability to coordinate the movements of the arms, legs, and torso together in activities where the whole body is in motion.

Gross body equilibrium: Ability to maintain balance with non-visual cues.

Stamina: Capacity to sustain maximum effort requiring cardiovascular/pulmonary exertion over long periods.

Table 1. Examples of tests available to measure each physical ability*

Static Strength	Arm pull
	Dynamometer Grip Strength
	Leg lift
Dynamic Strength	Rope Climb
	Push-ups
	Bent arm hang
Explosive Strength	50-yard dash
	Broad Jump
	Vertical Jump (Versitonic**)
Trunk Strength	Leg lifts
	Sit-ups
	Isometric abdominal
Extent Flexibility	Twist and touch test
	Sit and Reach
	Arthrodial Protractor**
Dynamic Flexibility	Rapid, repeated twisting, and bending-over
	Floor touching test
Gross Body Coordination	Cable jump
Stamina	12 minute walk/run
	Step test
	Treadmill Test**

*More complete descriptions, including conditions of administration, may be found in Fleishman (1964), Fleishman and Reilly (1992), and Myers et al. (1993).
**Tests available from Lafayette Instruments, Lafayette, Indiana 47603.

Extensive definitions, based on research, have been provided elsewhere, along with available tests, for their conditions, administrations, and apparatus for measuring these abilities. Table 1 provides examples of tests with high loadings on each ability factor. These measures have been shown to have high reliabilities, and normative and developmental data based on measures of each ability have been presented elsewhere (Fleishman, 1964; Fleishman & Reilly, 1992).

RELATING THE PHYSICAL ABILITIES TO JOB REQUIREMENTS

The physical ability factors described, and their definitions, provide a framework for thinking about the abilities required for the performance of physically demanding tasks. These nine physical ability factors have been included as part of a more comprehensive taxonomy of human abilities, which also includes cognitive, psychomotor, and sensory-perceptual abilities (Fleishman, 1975; Fleishman & Quaintance, 1984; Fleishman & Reilly, 1992). A methodology has been developed for describing the ability requirements of jobs and job tasks in terms of the complete taxonomy of 52 abilities (Fleishman, 1975, 1979 & 1992; Fleishman & Mumford, 1988, 1991) or, more selectively, in terms of the nine physical abilities described in this entry. The Fleishman–Job Analysis Survey (F-JAS) (Fleishman, 1992) and its constituent Physical Ability Analysis (Fleishman, 1975) provide the job analysis method for linking the physical ability constructs described here to the requirements of occupational tasks.

In this job analysis methodology, each of the carefully defined ability definitions are presented, each with a corresponding 7-point rating scale containing empirically derived task anchors at high, middle, and low points on each scale (see Fleishman, 1992). Respondents (job incumbents, supervisors, or job analysts) rate the level of each ability required for particular jobs or job tasks on ability rating scales, providing a profile of the job's ability requirements.

Using these and related methods, the physical requirements of thousands of jobs have been determined, including police, electrical power plant workers, telephone line workers, tyre manufacturer workers, dockworkers who load ships, warehouse workers, steel mill labourers, court security personnel, electric and diesel train operators, paramedical personnel, refinery workers, military occupational specialities, gas pipeline workers, maintenance workers, and mechanics of different types. Other researchers can now add substantially to this list (Fleishman, 1988; Fleishman, Costanza & Marshall-Mies, 1999; Hogan, 1991). Interrater reliabilities are high and there is very high agreement between profiles of ability requirements obtained from incumbents, supervisors, and job analysts.

SELECTION AND VALIDATION OF PHYSICAL ABILITY TESTS IN JOB SETTINGS

This job analysis method selects tests that result in valid and fair assessment batteries (see Fleishman & Mumford, 1988). Generic tests of basic physical abilities and work-sample tests involving these abilities have been shown to yield substantial

criterion-related validities. In several studies, where specific comparisons were made, there was no superiority in validity of work-sample tests over a battery of generic tests. Multiple *R*s in the 0.50s are not exceptional and multiple *R*s in the 0.60s and higher have been achieved. Generic tests of basic physical capacities offer the flexibility of differential weighting within the same battery of tests across different jobs. A nationwide industry study of 45 power utilities showed the generality of these validities across a variety of situations and subgroups (Cooper et al., 1981). There is no evidence for differential validity as a function of gender or race.

These studies demonstrate empirical criterion-related validities of physical ability tests. Other studies have validated the generic tests selected against job sample tasks specifically designed to emphasize different physical capabilities (Hogan, Ogden & Fleishman, 1979; Wunder, 1981; Myers, Gebhardt, Crump & Fleishman, 1993). This is further evidence of the construct validity of these physical ability tests.

Since the tests with most adverse impact on women (i.e. tests of static and dynamic strength) are often the most valid, it becomes particularly important to demonstrate their job relevance and validity across gender groups. Attempts at reducing adverse impact, at the expense of validity, may not be in the best interests of the female applicants or the organization, if the result is subsequent injury and lower job performance.

A conclusion from this research is that tests of practically every category of physical ability identified have shown significant validity for some job or other. Thus, tests of Extent Flexibility and Gross Body Equilibrium have shown validity for some jobs, but tests of Static Strength have shown validities for many more jobs. Some, but relatively few, physically demanding jobs require Explosive Strength or Stamina, since few jobs require activities such as running, jumping, or prolonged cardiovascular activity – but they are critical for some jobs. Examples of jobs requiring high levels of different physical abilities are:[1]

Static Strength: fire fighter, ambulance attendant.
Dynamic Strength: road repavers, steel mill workers.
Explosive Strength: lifeguards, police officers.
Trunk Strength: auto mechanics, plumbers.
Extent Flexibility: warehouse order selector, telephone line worker.
Dynamic Flexibility: fruit harvest worker, wall paper hanger.
Gross Body Coordination: basketball player, ballet dancer.
Gross Body Equilibrium: high-rise construction worker, gymnast.
Stamina: firefighter, mountain trail guide.

RELATING PHYSICAL ABILITIES TO MEDICAL SYMPTOMATOLOGIES AND IMPAIRMENTS IN JOBS

The importance of providing relevant information about job requirements that can be linked to information about disabilities, medical symptomatologies and diagnosis, and rehabilitation is increasingly recognized (Fleishman, 1999). Disability assessment programmes require better information about the job tasks that individuals with different disabilities can and cannot perform safely and effectively. One line of research involved classifying jobs in terms of common levels of requirements in each of the F-JAS physical ability scales (Fleishman & Quaintance, 1984). Occupational medical specialists were able to link disqualifying symptomatologies in relation to the different levels of job ability requirements (e.g. Fleishman, 1988; Hogan, Ogden & Fleishman, 1978; Fleishman & Hogan, 1978). This kind of information is valuable in assessing whether workers can return to their jobs or whether they can do other jobs. Other applications of these ability scales involved development of a computerized support system integrating information about the physical requirements of jobs with diagnostic procedures practised by physicians for use in occupational health and personnel services (Halpern, 1996).

FUTURE PERSPECTIVES AND CONCLUSIONS

Physical abilities measurement has become an active area of research with many conclusions possible about the constructs needed to describe physical performance, the distinctions between them, and their limits and generality across different kinds of physical performances. Tests

have been identified to reliably measure each physical ability and job analysis methods have been developed to identify the job tasks which require different physical abilities. These methods have been shown to result in tests with criterion-related validities predicting performance of individuals in a wide range of jobs involving physically demanding tasks.

A more recent encouraging development has been the use of the physical ability concepts and methods in disability assessment programmes (Fleishman, 1988 & 1999). More research is needed on how medical specialists can utilize this information in making more reliable and valid decisions about jobs that individuals with different medical impairments can and cannot do effectively and safely.

In other studies (e.g. Fleishman, Gebhardt & Hogan, 1986), the linkage of information obtained from the rating scale methodology with physiological and ergonomic indices of work capacity was demonstrated. It was shown, for example, that ratings using adaptations of Borg's Rated Perceived Exertion (RPE) Scale (Borg & Ottoson, 1986) predicted actual (independently measured) metabolic costs of performing a wide range of tasks. It was possible to predict metabolic costs across a wide array of jobs from the subjects' ratings of perceived effort even if the subjects had not actually performed the tasks.

These scales also were shown to predict ergonomic indices of work performance. It was shown, for example, that the weights of the objects moved was more related to perceived exertion than the distances the objects were moved (over the distances examined). These types of studies have promise for predicting and reducing physical exertion requirements in job situations, through job redesign.

It should be pointed out that the disciplines of exercise physiology and ergonomics have much to tell us about physical capacities in the work place. Future research should explore the further integration of human performance, physiological, and ergonomic concepts and methodologies in the predication and understanding of work performance in physically demanding jobs.

Note

1 Fleishman and Reilly (1992) provide many more examples of jobs and tasks requiring each ability, along with description of tests available to measure each ability and detailed definitions of each ability.

PLANNING

INTRODUCTION

The scientific literature about planning provides multiple definitions of the construct because planning has many components and because scholars have focused on different aspects of planning (e.g. Miller, Galanter & Pribram, 1960; Schank & Abelson, 1977; Zelazo, Carter, Reznick & Frye, 1997). A composite definition presents planning as 'a set of complex conceptual activities that anticipate and regulate behaviour. Planning relies on representation of the environment, anticipation of solutions to problems, and then monitoring of strategies to see whether they meet the problem and follow the plan. To plan is to act simultaneously on three levels: in the reality of the problem, in accordance with an imagined scheme [to reach the desired solution], and in the role of mediator between the scheme and the behaviour' (Scholnick & Friedman, 1987: 3).

WHY IS IT IMPORTANT TO ASSESS PLANNING?

Partly because of the complexity of planning and partly because researchers focus on different components of planning, the scientific knowledge about why, how and when people plan is not comprehensive or detailed. It is important to continue to refine methods of assessing planning for several reasons. First, effective planning is associated with efficiency and success in achieving goals, whereas deficits in planning are associated with learning disabilities and retardation. In addition, planning is pervasive across all areas of human life, yet does not occur in every situation.

It is therefore important to determine the cultural, social, and task-specific conditions under which people plan or fail to plan, as well as conditions that are conducive to effective and efficient planning when people do plan. Furthermore, planning has been shown to characterize behaviour at all ages, but the evidence detailing the developmental course of planning skills is incomplete.

ASSESSMENT METHODS

Test developers have generated different methods to assess planning skills according to their conceptualization of planning and the developmental status of the persons evaluated. Detailed information about the different tasks can be found in Friedman, Scholnick, and Cocking (1987), Friedman and Scholnick (1997), and Denckla (1994).

Structured and Abstract Problem-Solving Tasks

Much of the scientific literature about planning is based on tasks in this category, and these types of tasks emerged before other types were conceptualized. Perhaps the most well known abstract problem-solving task is the Tower of Hanoi (TOH; Denckla, 1994; Scholnick, Friedman & Wallner-Allen, 1997), which has been used with both adults and children. The standard task utilizes three identical pegs evenly spaced across a rectangular board. A fixed number of rings differing in size are placed on one or more of the pegs in varying patterns which depend on the problem to be solved. The task calls for rearranging the rings to match a configuration different than the original while obeying the rules of the game. Rules include never placing a larger ring on top of a smaller one (size constraint), moving only one ring at a time, and placing rings only on pegs.

Variants of the TOH (e.g. Klahr & Robinson, 1981; Welsh, 1991) were created to simplify the task demands. Methods of simplification include providing a visual representation of the solution, using cans of different sizes instead of rings, and tapering the pegs. The latter two methods were meant to remind the player of the size constraint rule. Additional means of simplifying the task for younger players include colour coding the rings or cans and embedding the task into a story about three monkeys of different size who like to jump on trees. The Tower of London is another variant of the TOH. It utilizes three coloured beads that are to be placed on pegs of three different heights. As in the other tasks, the goal is to achieve a prescribed solution in the minimal number of moves while obeying a set of constraints.

Tasks Simulating Real-Life Situations

Psychologists discovered that children's cognitive performance is more advanced than anticipated when test problems are embedded in familiar domains of knowledge. In order to assess planning in this more ecologically valid way, psychologists developed planning tasks that simulate real-world situations with which children are familiar. In these tasks, testers require children to carry out a set of activities while obeying task constraints in settings such as a mock neighbourhood, grocery store or classroom. To demonstrate, in the grocery-store task, a child is presented with a model store with pictures of items along the aisles and items to be retrieved. The child is then asked to get the requested items in the shortest possible route. Other simulated real-life tasks include planning a birthday party or beach trip. Another simulation task is to present children with meaningful vignettes in which story characters must develop plans to solve problems. The children are then asked to create plans to solve the problems faced by characters in the vignettes.

Interviews and Questionnaires

A less-common method of assessing planning is to ask people what aspects of their life they think require planning and what plans they use to fix and prevent problems. This methodology is used with individuals across the lifespan. In this approach, adults might be asked to think about a recent problem, conflict or challenge and describe its details; children might be asked about something they have had to work hard on, something that bugged them or something that had to be fixed. Once they describe the problem, they are asked about their anticipation and prevention of the problem (Berg, Strough, Calderone, Meegan & Sansone, 1997). The interview/questionnaire approach also has been used to assess

contraceptive use among adolescents (Adler, Moore & Tschann, 1997).

Observations

The least frequently used approach to assessing planning behaviours is direct observation. In this approach, investigators observe speech and behaviour that indicate goal setting and planning, as well as contexts that lead to effective and efficient goal achievement. For example, investigators have observed whether research scientists are more productive using specific, challenging goals or the goal of doing one's best (Locke, Durham, Poon & Weldon, 1997). The observation method is used in child and adult populations and in solitary as well as interactive planning situations. Methods for coding such planning vary in detail and complexity. They include approaches such as transcribing and coding dinnertime discussions between family members (Gauvain & Huard, 1999) and creating Time-Event Matrices based on actions observed during hypothetical planning situations (Streufert & Nogami, 1997).

FUTURE PERSPECTIVES

We recommend three means of improving the assessment of planning. First, planning involves multiple skills: representing a problem, setting a goal, deciding to plan, creating a plan, implementing and monitoring the plan, and reviewing outcomes (e.g. Scholnick & Friedman, 1987). It is possible that people have different profiles of skills when it comes to planning, with some stronger on some aspects of planning (e.g. setting goals, creating a plan) while others are stronger on other aspects (e.g. implementing the plan, monitoring implementation). Yet, at present, researchers and clinicians tend to measure a single component of planning skills (e.g. efficiency), rather than performance on all of the various sub-components of planning. We recommend that testers create individual *profiles* of planning skills in order to understand individuals' strengths and weaknesses on each sub-component of planning. Such profiles have practical implications. For example, organizations could use profiling to assign tasks to employees based on their differential strengths.

Second, existing assessments should be analysed to determine which specific components of planning they assess. Before individual profiles and thorough assessment batteries for planning can be created, testers need to know which specific cognitive or behavioural demands (i.e. sub-components) a task requires, as well as the degree to which those demands are central to success on the task. Although there are a few exceptions (e.g. Scholnick, Friedman & Wallner-Allen, 1997), such task analyses have not been prevalent and would be useful.

Third, performance on planning tasks in part reflects the values of the culture and the individual, familiarity with the requirements of the task, and motivation to engage in planning. While the importance of such moderators is self-evident, current assessments of planning do not control for individual differences on such moderators. We recommend that moderators of planning be evaluated and controlled in assessment batteries of planning. In summary, the field of planning assessment has done much to quantify and understand a tremendously complex task that involves individual, cultural, and contextual variables; however, more refined means of assessment are needed to further clarify the interplay of the multiple skills involved in planning.

CONCLUSIONS

The assessment of planning is difficult because planning is multifaceted, is used in almost all of life's arenas, and is influenced by familiarity with task characteristics and by personal values and motivation. Yet, reliable methods of assessment that are sensitive to age differences and to cognitive deficits have been devised and used both in research and in clinical evaluation. Methods of assessment include abstract problem-solving tasks, tasks simulating real-life situations, and interviews, questionnaires and observations. These methods could be improved upon by the creation of assessment batteries that tap (a) all components of planning and (b) factors moderating performance on planning tasks.

PLANNING CLASSROOM TESTS

INTRODUCTION

Any instruction requires continuous student assessment for the purpose of enhancing the quality of the instructional processes and improving student learning. The test development process needs planning and systematic procedures for the whole process of test construction in order to enhance the reliability and validity of the assessment results to be used for instructional decisions. This entry gives a general guideline in planning and analysing classroom tests and future developments and trends in classroom assessment as well.

STEPS FOR PLANNING CLASSROOM ASSESSMENT

Student assessment within the framework of classroom instruction requires planning of the following tasks:

1 Determining the purpose of the test
2 Preparing test specifications
3 Writing test items
4 Assembling test forms
5 Administering tests
6 Evaluating test results

Each step has its own procedures and requires detailed descriptions of planned activities.

Determining the Purpose of the Test

In using classroom tests, teachers may have a broad purpose such as 'grading' at the end of a semester, but in some instances they may rather focus on a specific purpose such as 'whether students demonstrate understanding of mole concept in a non-routine problem setting'.

No matter how broad or narrow the decisions to be made, teacher-made tests are used for various general purposes, as indicated below:

- Understanding entry characterisitics of students,
- Monitoring learning progress of the students throughout the instructional process,
- Understanding the reasons for persistent learning difficulties among students,
- Grading general achievement level of students at the end of instruction,
- Evaluating the effectiveness of instructional processes and materials,
- Providing feedback for students to monitor and assess their learning progress,
- Enhancing student understanding of their interests and progress,
- Identifying students' strengths and weaknesses in terms of different aspects of subject matters they cover,
- Identifying students' strengths and weaknesses in terms of cognitive processes to be developed,
- Providing information for the school administration to convey and implement curricular, extracurricular and counselling activities,
- Selecting students for some remedial or advanced level courses,
- Conducting research studies in terms of students' learning and progress.

In a broader sense, even though assessment results are used for different purposes, the core of the classroom tests focuses on student needs and expectations, and the results are generally used for selection, placement, instructional, pedagogical, and administrative decisions. Focused on instructional processes, classroom assessment is generally organized around placement, formative, diagnostic, and summative decisions (Bloom et al., 1971; Gronlund, 1993; Nitko, 1989).

In the very first step of planning classroom tests, standards to which students' performance will be compared and evaluated should also be determined. Teachers need to specify a minimum competency level either by referencing performance of a group, or setting a minimum standard task that students should demonstrate. The nature of the minimum competency level to be used could be norm-referenced or criterion-referenced, depending on the purpose of testing. For instance, grading may require norm-referenced interpretations; on the other hand, preparing students for a new learning task may require a minimum level of understanding of a set of concepts which could be done within the framework of criterion-referenced testing.

Preparing Test Specifications

In this step three questions should be addressed in order to plan a classroom test: (1) What knowledge such as facts, concepts, principles, generalizations, algorithms, etc., are necessary for students? (2) What content domain is necessary for students? and (3) What cognitive skills and processes are planned to be developed to deal with acquired knowledge and content domain? The answers to these questions are found in the table of specifications (content versus process matrix) where, in a two dimensional chart, it is possible to list all the content of the course, and the knowledge and cognitive processes to be developed in students. In the 1970s Bloom's taxonomy of educational objectives was considered as one of the pioneers in categorizing learning outcomes of students in cognitive domains (Bloom et al., 1971). In its broader sense, Bloom's taxonomy of educational

objectives covers knowledge, comprehension, application, analysis, synthesis and evaluation levels. Other taxonomies proposed in the following years have more or less the same idea of the hierarchical structure of human thought. For instance, Williams and Haladyna proposed a taxonomy consisting of recalling, summarizing, predicting, evaluating, and applying steps in developing a thinking schema in line with facts, concepts, and principles (Roid & Haladyna, 1982). However, with the impact of cognitive psychology on teaching and learning, more emphasis was given to complex cognitive skills, and assessment became more process and product oriented rather than tracing individual performances on paper-and-pencil tests (Calfee, 1995). The taxonomy proposed by Royer, Cisero, and Carlo (1993) seems promising and pioneering to deal with higher order thinking skills of students within the framework of cognitive psychology, introducing measures such as: (a) knowledge acquisition, organization and structure; (b) depth of problem representation; (c) mental models; (d) metacognitive skills; (e) automaticity of performance; and (f) efficiency of procedures.

A content versus process matrix serves two important purposes. First, it enhances the content validity of the test to be developed by indicating the weight given to each content area and cognitive processes of instruction; second, it guides teachers to decide the item format to be chosen in measuring each specific learning outcome.

Writing Test Items

The conventional approach in item format classifies the types of questions teachers use as objective versus open-ended. Multiple-choice, true–false, matching, and short answer formats are considered as objective item formats. On the other hand, restricted response and free response questions are considered as open-ended formats.

In this step there are two groups of decisions to be made in writing test items.

In terms of item content, three issues may help teachers to develop defensible and valid questions:

1 Assessment of intended learning outcomes with respect to cognitive processes and subject matter should be accomplished without the influence of other unintended learning outcomes. Measurement of reading ability and/or arithmetic skills rather than basic concepts and principles in a science test may jeopardize validity of classroom assessment. Item content should only emphasize the intended learning outcome depicted in the content versus process matrix.
2 An item format should be used which is congruent with the specifications set at the beginning of the instruction. Ability to develop a personal stance based on written textual information cannot be assessed by a multiple-choice item format. Performance-based assessment seems more suitable to measure this learning outcome. The teacher needs to match the specific learning outcome and the most efficient item format to be used.
3 The item should present a stimulus which is closest to a real life situation. Assessment of computer skills by a paper and pencil test is not a stimulus which is authentic in terms of expected learning outcome. Performance-based assessment in front of a computer is a more appropriate assessment strategy in this respect in terms of modelling a real life situation.

In terms of technical issues in writing test items, teachers need to decide two important things: (1) What difficulty level is ideal for the items to be developed? and (2) What guidelines are to be used in producing the items? For a norm-referenced test, item difficulty should match the ability level of the group; that is to say, for defensible item analysis results, item difficulty and item discrimination indices should be at the desired level. On the other hand, if the purpose of assessment is to make criterion-referenced inferences, the only thing teachers should consider is to question whether the item content represents what is implied in the specifications developed at the very first step of the test development process. Discrimination is important in terms of mastery–non-mastery groups, which is conceptually different than norm-referenced discrimination indices.

There are item writing guidelines proposed by different researchers (Ebel, 1972; Gronlund, 1993; Haladyna, 1994; Thorndike, 1971). The main issue in developing guidelines for item writers is enhancing the quality of the test items and increasing the validity and reliability of the whole

measurement process. Considering different item formats, different suggestions were developed by researchers. In general, the following issues should be considered by classroom teachers for all types of test items to be used for student assessment:

- Items should be congruent with the test purpose and specifications.
- Items should deal with an important aspect of subject matter.
- Items should be free from irrelevant information which is not necessary for the learner.
- Ambiguous statements should be avoided.
- Higher order thinking skills should be emphasized instead of memorized information.
- Language should be clear enough to communicate with the students.
- An answer to one item should not be a condition for solving the next item.
- Item content should be free from contextual information that may create bias against certain groups.
- Item content should be free from negative phrases.

Writing defensible items may be more difficult for teachers in certain formats than others. For instance, writing an item measuring higher order thinking skills is always more difficult than writing items in assessing factual text based information. No matter which item format is to be used, writing defensible test items requires good knowledge of the subject matter, understanding of different item formats, their functions and limitations, and experience in teaching and item writing activities.

Assembling Test Forms

In creating test forms teachers should plan for (1) selecting a representative sample of items which reflects the weights in the table of specifications; (2) grouping items with respect to subject matter, or item formats; (3) ordering items within each group – such as from easier to difficult, or some other logical order; and (4) general direction and directions to be presented at the beginning of each subtest encompassing purpose of the test, number of items, information about item format, time duration, scoring schema, etc.

Administering Tests

For a standard classroom assessment, the following questions should be considered during administration:

- Are physical conditions suitable for the students to take the test?
- Are students motivated for taking the test?
- Are testing day and time suitable for the students?
- Is enough time given for students to attempt all the items of the test?
- Are there any external factors affecting students' performance on the test?

A standard test administration process definitely improves technical quality of the test scores, such as reliability and validity.

Evaluating Test Results

Test results are analysed at the test score level and item score level.

Test score level analysis entails the distributional characteristics of the total scores and subscale scores. Reporting test scores in terms of content specifications such as computation, word problems, geometry subscales in a mathematics test, and cognitive processes such as solving non-routine problems, proposing a hypothesis and making generalizations in a science test will have more value in terms of students' learning progress rather than reporting a total test score. Criterion referenced interpretations of mastery–non-mastery decisions need to clarify the question of, 'What is different between the two students who are above and below the cut off score in terms of knowledge acquired and cognitive skills developed?' This is an issue discussed under the problem of standard setting (Hambleton & Jurgensen, 1990). For instance, if a mathematics teacher wants to define a standard for a summative test, he/she should be able to say that students who are above the cut off score are able to successfully demonstrate the ability to solve a non-routine problem. Having this expected performance defined, the next step should be to determine above which score level students are able to demonstrate that expected skill. Norm referenced interpretations of the scores of an achievement test can be carried out with respect to percentiles or standard score format.

Item level analysis requires obtaining some item statistics and deciding on whether: (a) items function as intended or not, and (b) students have major difficulties with respect to content and cognitive processes assessed by the item.

Types of decisions to be made play an important role in determining the item analysis strategies. If the results will be interpreted as norm-referenced, item difficulty, item discrimination and endorsement of students in each of the alternatives (if the item is multiple choice) must be evaluated.

Criterion-referenced interpretation deals with items which elicit evidence of which students demonstrate a satisfactory level of competence as a result of training. Thus, a couple of different indices are basically comparing (a) performance of two criterion groups on a single test item such as mastery versus non-mastery, instructed versus uninstructed groups, or (b) pre–post test gained scores in the item level to evaluate sensitivity to instructional processes (Crocker & Algina, 1986).

FUTURE PERSPECTIVES

Two mainstreams seem to influence classroom assessment in the future.

These are: (1) restructuring testing practices around performance-based assessment in addition to conventional student assessment procedures, and (2) extensive use of computer technology during test construction processes and student assessment.

There was increased attention to criterion-referenced testing in classroom assessment in the 1970s under the influence of behaviourist approaches to educational processes. Behaviourism affected student assessment because of two reasons. First, behaviourist description of human learning made it possible to define and describe all the student learning outcomes easily, and these enabled test developers to link each question in a testing situation with a clearly defined test specification. Second, the ease of establishing the link between the learning outcome and test question made it possible to trace student progress through instruction with a clearly defined behavioural domain.

Assessment of complex learning processes became more prominent in classroom assessment with the increasing impact of cognitive psychology and multiple intelligence theory on educational practices (Armstrong, 1994; Haladyna, 1997; Snow & Lohman, 1989). Thus, in a classroom assessment, instead of assessing factual and declarative information, more attention is given to assessment of communicating, measuring, investigating skills, as well as organizing, problem solving and decision making processes. Approaches such as performance based, authentic, alternative assessment, and portfolio assessment, are used interchangeably to emphasize any tool to observe students' learning process through which they demonstrate understanding of concepts and principles by performing a task in the same way they would act outside of school. These tasks require use of knowledge and higher order thinking skills as well as habits of mind (Herman et al., 1992). Portfolio assessment, on the other hand, consists of a collection of students' work, such as projects, term papers, compositions, etc., to trace student progress (Kubiszyn & Borich, 1996). Development of performance-based assessment schema is not different than the steps explained in the previous part of this entry, except that testing is integrated into teaching and learning activities more than in the conventional assessment approaches. The critical issue in performance-based assessment is preparation of scoring rubrics. An extensive discussion on types of rubrics may be found in Haladyna (1997).

The role of computers in testing is generally limited to high stake standard test administration. However, during the teaching and learning process, computers are commonly used as a supplementary instructional aid. More frequent use of computers will be indispensable in classroom testing in the future during the processes of test preparation, test administration, and test scoring.

Computer technology helps teachers in the following respects:

1. Provides a large item pool to facilitate a representative sample of the learning domain for a valid content coverage as long as items are coded with respect to content and cognitive domain specifications.
2. Provides the technology for producing high quality authentic test items, which is not possible with a paper and pencil test, with the use of colours, sound, and three-dimensional graphical representations, etc.
3. Facilitates seamless instruction where smooth transition between teaching and assessment is desirable.

4 Provides a base for portfolio assessment by recording students' work in order to monitor individual progress on a given task.
5 Matches examinee ability with the difficulty of test items through the use of adaptive test administration.
6 Improves students' interest during testing and enhances validity of measurement.
7 Increases test security in the classroom environment.
8 Provides opportunities to assess some aspects of important learning outcomes which are not possible by paper-and-pencil tests, such as speaking skills and listening comprehension in learning a foreign language.

CONCLUSIONS

Planning a classroom test is a professional task. The general aim of classroom assessment is to enhance student learning. Within this framework, setting a clearly defined purpose and linking all the assessment attempts with a clearly specified content and cognitive processes domain may help student learning progress. In the last decade, performance-based assessment gained more importance than any other classroom assessment. Therefore, teachers need to deal with more complex learning outcomes. The use of computer technology with the integration of conventional and performance-based approaches might increase the quality of assessment every classroom teacher aspires to accomplish.

POST-OCCUPANCY EVALUATION FOR THE BUILT ENVIRONMENT

INTRODUCTION

Post-Occupancy Evaluation (POE) refers to studies that assess the operation, status, and usability of a physical setting at some point after construction is completed and users move in. These studies are typically undertaken to assess the success of the design in meeting stated goals, identify problems needing attention, or provide 'lessons learned' for the design of another facility. POEs can be qualitative or quantitative in approach, involving a variety of data gathering techniques, including surveys, behavioural observations, behavioural trace or archival data. They range from brief and inexpensive individual studies to large scale, longitudinal, multi-site efforts. POEs are conducted by facility owners, particularly those seeking to improve repeatedly built settings, designers trying to inform their practice, and researchers looking to understand human–environment relations.

DEFINITION OF POST-OCCUPANCY EVALUATION

A Post-Occupancy Evaluation (POE) is an assessment of a designed environment after it has been constructed and occupied to see how well it operates in terms of criteria that address function, efficiency and comfort of its intended uses and users. POE makes use of the research methods, instruments and data analysis techniques of the social sciences to provide a systematic evaluation of the setting. Zimring (2002) defines POE as:

> *... the systematic assessment of the process of delivering buildings or other designed settings or of the performance of those settings as they are actually used, or both, as compared to a set of implicit or explicit standards, with the intention of improving the process or settings.* (Zimring, 2002)

POE has been compared to programme evaluation in providing an opportunity to 'pause and reflect on the impact ... to assess concept, implications and utility, and to judge and improve planning, effectiveness and efficiency...' (Rossi & Freeman, 1985). Shibley (1982) notes that design without evaluation is like 'action without reflection'. As such, POEs can serve not only to modify a specific building or setting type, but to improve design practice.

POE can include technical assessments of engineering systems (lighting, HVAC, etc.). It is distinctive, however, in its 'focus on building occupants and their needs ... [providing] insights into design consequences of past design decisions and the resulting building performance' (Preiser, Rabinowitz & White, 1988). Anderson and Butterfield (1980) make a distinction between POE as the study of functional use (social and behavioural issues) versus Post-Construction Evaluation studies of engineering systems.

POE is the last stage of Zeisel's (1981) oft-cited design cycle, which describes the evolution of a design project from concept, through programming, design, and construction, concluding with the POE. In Zeisel's model, the prime value of a POE is to provide information that informs the next iteration of the design cycle, and adds to the general base of information about that building type and environment–behaviour relations.

BRIEF HISTORY OF POST-OCCUPANCY EVALUATION

Bechtel (1997) notes that POEs have been conducted for decades, not as formal studies but in reviews and assessments of buildings done by architecture professors and their students. POE as a self-conscious and rigorous activity, however, began in the 1960s as social scientists worked to create methodologies that could

Table 1. Some dimensions of Post-Occupancy Evaluations

Evaluator	Researchers, Designers, or Clients		
Scale	Single Site versus Multi-Site One point in time versus Longitudinal or Multi-generational		
Depth	Level 1 Benchmarking	Level 2 Detailed case study	Level 3 Diagnostic study of issue or space
Purpose	Comparative versus Generative

Content/Process	Focus on information versus Focus on user involvement and participation		

provide support for designers who were trying to provide socially responsive facilities (see Zimring, 2002; Friedmann, Zimring & Zube, 1978; Preiser, Rabinowitz & White, 1988; Shibley, 1982). The settings studied in many early POEs were those readily available to the university-based researchers (e.g. university dormitories), or sites of special interest to behavioural and social scientists (e.g. psychiatric settings, etc.).

Designers have looked to POEs for design-decision support, particularly when pressured to make choices among a set of uncertain options (Kantrowitz & Farbstein, 1996). Significant support for the use of POE in the United States was provided by its inclusion in the Senate Public Buildings Act of 1980, section 108, which required the use of POE to 'determine and improve effectiveness of existing and planned public buildings providing a safe, healthful, economical, conveniently located, energy-efficient and architecturally distinguished accommodations for federal agency offices'.

Early studies were often of one site at one point in time (such as the POEs of psychiatric facilities by Osmond [1959], or Ittleson et al. [1970]. The exception is Wheeler and Miller's evaluation of four generations of college dormitories (Wheeler, 1985). While 'one-off' evaluations remain the most common there have been a number of significant efforts at creating more broad-based studies that look across a range of settings, such as POEs of a range of government buildings for the California DGS (DGS, 2001), of United States Postal Service facilities (Kantrowitz & Farbstein, 1996), of jails and prisons (Wener et al., 1996) and of office settings (Brill et al., 1984). Zimring (2002) notes that increasingly POEs are becoming proprietorial and are addressing more diverse types of settings.

CATEGORIES

Preiser et al. (1988) have described three levels of POEs: (1) brief indicative studies; (2) more detailed investigative POEs; and (3) diagnostic studies aimed at correlating environmental measures with subjective user responses (see Table 1). Level one 'brief indicative' studies, according to this categorization, are benchmarking studies – broad but shallow – gathering comparative data across a potentially large number of sites. They provide baseline data on a variety of issues and spaces across facilities so that exceptionally good or poor settings can be identified for closer study.

This closer look comes in level 2 or level 3 POEs. Level 2 investigations provide in-depth studies of individual sites, either to find and fix problems or to note and promulgate particularly effective solutions. Level 3 diagnostic studies look more closely at specific issues or spaces rather than a particular facility. If, for instance, a level 1 benchmarking should indicate that wayfinding in corridors is a pervasive problem, or that nursing home kitchens are rated poorly, a level 3 POE

might be initiated to look at that issue or space more closely across a variety of institutions.

POEs have also been classified as being either comparative or generative in purpose (Wener, 1989). Comparative studies (like level 1 and in some cases level 3 POEs) have the purpose of comparing a setting to another setting or to itself at a different point in time. They are undertaken to test a hypothesis or to assess the success of a design programme. Generative POEs, on the other hand, are undertaken to develop ideas and provide information that can directly support the creative design process.

ASSESSMENT INSTRUMENTS AND TECHNIQUES

As in other areas, POE assessment techniques and instruments have evolved over time, with experience and changing needs. User self-report of satisfaction via questionnaire or interview remains the most common type of data in use, because of the relative ease and cost of collecting, analysing and reporting survey data (e.g. Wheeler, 1985; Anderson & Weidemann, 1997). Comparative POEs, whose primary purpose is to assess satisfaction within or across sites, commonly use objective survey instruments, such as questionnaires with Likert-like scales (such as in studies of office workers by Brill et al., 1984 or Picasso, 1987).

Generative studies, however, which seek to provide programming information for designers, are more likely to use open-ended instruments that ask questions like 'how well does this space work for you' and 'how would you change it?'. A good example is the 'walk-through' evaluation (Gray et al., 1985) in which researchers tour a space, accompanied by users, asking questions from a structured interview schedule as they go to develop an understanding of user needs and concerns.

Some survey instruments are generic and meant for a broad range of settings (Vischer, 1989 and Preiser et al., 1988 provide useful examples of such assessment forms), while others are highly specific, tailored to a particular setting type, like hospitals (Cantor & Kenny, 1977) or jails (Wener et al., 1993). In either case, there has been a trend toward standardization, developing statistical baselines and norms to aid in comparisons and understanding of relative well-being. Zimring (2002) notes that Heerwagen has recommended using a 'balanced scorecard' approach that addresses issues such as financial performance, impact of the building on the business process, growth and satisfaction of employees and impact on other stakeholders (Heerwagen, 2001).

Bechtel (1997) and Zimring (2002) discuss the benefits of using multiple methods to increase confidence in results through convergence of information from various sources. Multi-method POEs can make use of archival data, trace data, and behavioural observations, in addition to self-report surveys (see Zeisel, 1981, for a discussion and examples of these methods).

POEs can be used as part of a broader organizational change process. If a goal of the evaluation is to give users greater participation in and ownership of the design, there is likely to be an emphasis on group process and methods, such as focus group interviews, in gathering information (Schneekloth & Shibley, 1995).

EXAMPLES OF POST-OCCUPANCY EVALUATION

There are, by various estimates, thousands or tens of thousands of POEs, mostly individual case studies, many of which are unpublished or otherwise proprietorial. Bakos et al.'s (1980) evaluation of a geriatric facility is unusual as a quasi-experimental study with observations of resident social behaviour at four points in time over several years, before and after group design process meetings and spatial re-design. Their data demonstrated the positive impacts both of being involved in the design process and of the design interventions.

There is a growing list of examples of POE systems developed for institutional clients. Rosenheck et al. (1997) conducted eight POEs to assess technical issues and user satisfaction of embassies for the US State Department, addressing issues such as aesthetics, circulation, security and maintainability. They also developed an online database to make the results easily accessible.

Wener, Farbstein and Knapel (1993) developed a package of POE instruments for the National Institute of Corrections to assess jail environments, including a physical setting checklist, survey forms for administrators, facility

managers, and programme staff, questionnaires for officers and inmates, and forms and instructions for conducting behaviour observations. This package was used in new facilities in Florida, California and Massachusetts.

Underhill (1999) describes his evaluations of the impact of store design on customer behaviour, mostly using behavioural observations and photography, in many kinds of retail settings. These studies have led to modifications of design that have demonstrably improved sales.

Kantrowitz and Farbstein (1996) conducted POEs of post office facilities for the United States Postal Service that have been important in the development of design standards for the USPS operation. (See Preiser et al., 1988, Zimring, 2002, and Wener, 1989 for more examples of evaluations.)

FUTURE PERSPECTIVES AND CONCLUSIONS

Individual POEs will inevitably continue to be a useful source of information to assess the success of settings and provide recommendations for future design. It seems likely, however, that the trend will continue toward increased development of standardized POE packages for use within or even across facility types. Even places as diverse as schools, offices and jails, for instance, have spaces and characteristics in common (e.g. maintenance, kitchens, workstations). Standardization allows for useful comparisons across time and place, improving the ability of POEs to provide general lessons and make theoretical contributions, although possibly at the cost of loss of information on the unique characteristics of a facility.

Information technology can help improve the availability of having POE data when and where needed. It is undoubtedly true that mistakes have been made because a designer or client was unaware of, or had no access to, relevant POE results. The development of online databases can make such information handy and accessible (see Zimring, 2002, for an example).

Gawande (2000) makes a case that critical incident studies by systems engineers were able to identify systematic problems in medical systems and eventually led to improved hospital practices and reduced death rates. A set of critical incident studies of the environmental design process, through a focused set of POEs, might also be able to identify systematic problems, and could improve design practice to reduce mistakes.

PRACTICAL INTELLIGENCE: CONCEPTUAL ASPECTS

INTRODUCTION

Practical intelligence has been one of the fastest growing areas of the field of intelligence over the past two decades. In a *Handbook of Human Intelligence* (Sternberg, 1982) published almost 20 years ago, the term practical intelligence did not even merit an entry in the index. In the more recent *Handbook of Intelligence* (Sternberg, 2000), the term practical intelligence has multiple entries in the index, and indeed, an entire chapter is devoted to the topic (Wagner, 2000). Because practical intelligence is a relatively new and evolving construct, this entry addresses issues concerning the nature of practical intelligence and its relations with other kinds of intelligence, in addition to the issue of how practical intelligence can best be measured.

THE NATURE OF PRACTICAL INTELLIGENCE

The merits of defining intelligence of any sort are not obvious. No particular definition of intelligence has become dominant, nor has defining intelligence proved to be a useful endeavour. In 1921, the editor of the *Journal of*

Educational Psychology asked 17 leading researchers to define intelligence. Their responses consisted of 14 different definitions and three non-replies. When leading researchers were given the same task 65 years later, the most notable characteristic of their replies was their variability (Sternberg & Detterman, 1986). Despite these limitations, examining working definitions of practical intelligence provides insight into what appears to be meant by the concept. Four working definitions will be considered briefly.

Exclusionary Definitions

An exclusionary definition defines something by characterizing what it is not. Frederiksen (1986) defined practical intelligence as cognitive responses to just about anything encountered outside the classroom setting. Although it is true that academic knowledge is useful in some everyday contexts, and practical knowledge can be important to aspects of school performance, there do appear to be differences between the typical problems found in the classroom and those encountered in everyday contexts beyond the classroom. Problems found in the classroom and on IQ-type tests tend to (a) be well defined, (b) be formulated by others, (c) come with all information required, (d) have a single answer, (e) have a single method of obtaining the correct answer, and (f) be unrelated to everyday experience. In contrast, the more practical problems of everyday life often are (a) poorly defined, (b) unformulated, (c) missing essential information, (d) characterized by having multiple solutions – each with liabilities as well as assets, (e) characterized by having multiple methods of obtaining each solution, and (f) related to everyday experience (Neisser, 1976; Wagner & Sternberg, 1985). Given the difficulties that arise from the ill-defined nature of practical problems relative to academic problems, it is fortunate that lessons learned over the years from everyday experience turn out to be applicable to solving the practical problems we encounter.

Practical Know-How

Studies of cultures that have been characterized as 'primitive' by Western societies produced interesting examples of practical know-how. In third world countries that have automobiles, considerable practical know-how can be required to keep them running in the absence of sophisticated test equipment and replacement parts. Automobile repair often involves adapting an object at hand to fix the problem (Berry & Irvine, 1986). Gladwin (1970) studied how the Puluwat people of Micronesia do ocean navigation without modern navigation instruments. They rely on a sophisticated system that is based on the idea that it is the islands that move rather than the canoe they are in. An initial course is set when leaving the harbour of origin by drawing imaginary lines from the canoe to known landmarks on the island they are departing. This course is maintained in a variety of ways, including making reference to the stars at night and the sun during the day. The destination island is found by looking for birds that are known to roost on land, odours and sounds associated with land, and changes in wind patterns or velocity that can indicate a land mass.

Wagner and Sternberg (Sternberg, Forsythe, Hedlund, Horvath, Wagner, Williams, Snook & Grigorenko, 2000; Sternberg, Wagner, Williams & Horvath, 1995; Wagner, 1987, 1997; Wagner & Sternberg, 1985) have studied practical know-how in the form of tacit knowledge. Tacit knowledge refers to practical know-how that rarely is formally described or taught directly (Wagner, 1987). According to this view, practical intelligence can be measured in a manner analogous to that used to measure academic intelligence. An IQ test is not a direct measure of academic intelligence. Rather, it represents a sample of academic knowledge that could have been learned over recent years. After making assumptions such as equal opportunity to learn the material, the inference is made that individuals who have learned the most have the most academic intelligence. Wagner and Sternberg developed samples of tacit knowledge for a variety of career domains. Using the logic of IQ tests, they assumed that individuals with more tacit knowledge had more practical intelligence.

Social Judgement

Given the important role played by others in our environment, and that intelligence often is conceptualized as the ability to adapt to and shape one's environment, it is not surprising that social judgement plays a central role in some conceptions of practical intelligence. For example,

Ford (1986) and Mercer, Gomez-Palacio, and Padilla (1986) describe practical intelligence as synonymous with social competence.

Practical Intelligence as a Prototype

Neisser (1976) suggested that it is impossible to define intelligence as any one thing. The most we can do is agree on a prototype that represents the ideal exemplar of intelligence. According to this view, the amount of practical intelligence that a given individual has is determined by the extent to which he or she resembles the prototype. Sternberg, Conway, Ketron, and Bernstein (1981) adopted this approach by asking laypersons as well as experts to rate how characteristic 250 descriptions were of an (a) ideally intelligent person, (b) academically intelligent person, and (c) everyday intelligent person. The ratings of laypersons characterized practical intelligence in terms of practical problem-solving ability, social competence, character, and interest in learning. The ratings of experts characterized practical intelligence in terms of practical problem-solving ability, adaptive behaviour, and social competence.

RELATIONS BETWEEN PRACTICAL INTELLIGENCE AND OTHER KINDS OF INTELLIGENCE

Most of the research relating practical intelligence to other kinds of intelligence was motivated by a desire to determine if practical intelligence was distinct from the kind of intelligence measured by the ubiquitous IQ test. The majority of these studies indicate that practical intelligence (a) is at best weakly related to academic intelligence, (b) is often a good predictor of real-world performance, and (c) consequently, the contributions of practical and academic intelligence to prediction are largely independent as opposed to overlapping (Sternberg, Wagner, Williams & Horvath, 1995).

Although it was important to show that practical intelligence was different than the kind of academic intelligence measured by IQ tests, this falls short of the larger goal of providing a comprehensive framework that integrates and relates practical and academic intelligence. Several promising frameworks will be described briefly.

Fluid and Crystallized Abilities

Horn and Cattell (1966) categorized intelligence into two different forms that have different lifespan developmental functions. Fluid abilities are abilities that are required for dealing with novelty in a situation. Fluid abilities reach their peak in the late teens and slowly decline thereafter. Crystallized abilities are conceptualized as acculturated knowledge. They may be maintained at high levels throughout adulthood. The distinction between fluid and crystallized abilities is sometimes described as that between the processes and products of learning. The different lifespan trajectories of fluid and crystallized intelligence fit the different lifespan trajectories noted for academic and practical intelligence. Performance on measures of academic intelligence peaks and declines much earlier than performance on measures of practical intelligence does.

Pragmatics and Mechanics of Intelligence

A view that is related to the distinction between fluid and crystallized intelligence is that of Baltes, Dittmann-Kohli, and Kliegl (1984). Intellectual functioning is divided into mechanics and pragmatics. The mechanics of intelligence refers to the content-free architecture of information processing and problem solving. The mechanics of intelligence corresponds to fluid intelligence. The pragmatics of intelligence includes accumulated knowledge and skill, similar to the concept of crystallized abilities.

Multiple Kinds of Intelligence

Conceptualizations that describe different kinds of intelligence routinely include practical intelligence. An example is provided by Sternberg's (1985) triarchic theory of human intelligence, in which practical intelligence is viewed as a kind of intelligence that is different from both analytic and creative intelligence. Another example is provided by Gardner's (1983) multiple intelligences theory, in which practical intelligence is

reflected in both intrapersonal and interpersonal intelligence.

MEASURING PRACTICAL INTELLIGENCE

Compared to the study of traditional IQ, the study of practical intelligence is in its infancy. It should not be surprising therefore that measures of practical intelligence are just being developed.

Sampling Tacit Knowledge

The most extensive effort to measure practical intelligence has involved sampling tacit knowledge using an approach that is analogous to measuring IQ. IQ tests do not measure 'intelligence' directly. Rather, they do so indirectly by sampling knowledge and skills that an individual has had an opportunity to acquire over recent years. By assuming equal opportunity and motivation for learning the information and skills, the *inference* is made that an individual who has learned more has more learning ability or intelligence. Evidence of this view of IQ testing is provided by the facts that simple vocabulary is the single best predictor of IQ, and IQ tests are virtually indistinguishable from achievement tests.

Measures of practical intelligence based on sampling tacit knowledge are constructed by interviewing individuals to identify domain relevant tacit knowledge. Scenarios are then constructed that describe situations or problems to be solved involving relevant tacit knowledge. Performance typically is scored by comparing an individual's responses to the responses of an expert panel. See Sternberg et al. (2000) and Wagner (1987, 2000) for detailed descriptions and examples of this methodology.

Other Approaches

In addition to sampling tacit knowledge, a variety of other approaches have been used to quantify practical intelligence. These range from obtaining ratings of an individual's characteristics to assess his or her similarity to an ideal prototype of practical intelligence, to work sample approaches in which individuals are given practical problems and their actual performance is scored or rated. See Sternberg and Wagner (1986, 1994) for examples of these other approaches.

FUTURE PERSPECTIVES AND CONCLUSIONS

Formal assessment of practical intelligence has largely been done in the context of researchers carrying out studies as opposed to actually being applied to make real-world decisions in the context of selection or training. Established procedures and measures used for selection are entrenched. Measures used today look much like measures used decades ago. Inclusion of measures of practical intelligence in real-world selection and training contexts is the next great challenge, one that will be achieved gradually over a long period of time. Examples are beginning to emerge. The University of Michigan is beginning to use a measure of practical intelligence for making admission decisions in their business school. The United States Defense Department has supported research into tacit knowledge measures for selection and training in military contexts. The success or failure of these early efforts will play an important role in the speed with which measures of practical intelligence become widely available and used.

PRACTICAL INTELLIGENCE: ITS MEASUREMENT

INTRODUCTION

Practical intelligence is one among various multiple intelligences that have been proposed in recent years. Sternberg and his research team (Sternberg et al., 2000: xi–xii) are the only researchers, however, to have undertaken a systemic programme to measure practical intelligence and to assess its criterion-related validity. They claim to have shown that it is not only independent of the well-documented general intelligence factor, *g* (Carroll, 1993; Jensen, 1998), but also 'arguably ... a better predictor of success' in life.

CONSTRUCTS ASSESSED

Sternberg and his colleagues do not actually measure practical intelligence, but what they refer to as its 'important aspect', tacit knowledge.

Practical Intelligence

Sternberg and his colleagues define practical intelligence as 'the ability to solve real-world everyday problems' and, most broadly, 'the ability to adapt to, shape, and select everyday environments'. It is 'what most people call common sense' (Sternberg et al., 2000: xi, 97–98).

Although *g* is known to be a very general ability (Carroll, 1993), Sternberg and his colleagues argue that there exists a second, separate general intelligence – a practical intelligence – because adapting to the real-world requires practical action but IQ tests measure only an 'inert', 'academic' ability. More specifically, they argue that there are two distinct spheres of human activity. The 'academic' sphere of activity is said to pose problems that are formulated by other people, well-defined, and complete; possess only a single correct answer and method of obtaining that answer; and are disembedded from ordinary experience and are of little or no intrinsic interest – in other words, the stereotype of an IQ test. In contrast, 'practical' problems require problem recognition and formulation; are ill-defined; require information seeking; possess multiple acceptable solutions; allow multiple paths to solution; are embedded in and require prior everyday experience; and require motivation and personal involvement.

This academic–practical distinction in the kinds of *tasks* that people confront in life is meant to establish a prima facie case that *g* is not really a general ability, because there must be different intelligences for the two kinds of tasks. Although this distinction among tasks may be useful for some purposes, it cannot moot a century of research showing that higher levels of *g* actually do provide individuals big practical advantages in everyday life, from level of job and income attained to health and longevity (Gottfredson, 2002, in press b; Schmidt & Hunter, 1998). In fact, higher levels of *g* are especially advantageous when tasks 'require problem recognition and formulation, are ill-defined, and require information seeking', attributes describing the tasks that the Sternberg team assigns to the 'practical' sphere of life.

Sternberg and his colleagues draw a second distinction to support the viability of their practical intelligence construct, namely that there are academic and practical forms of *knowledge*. This is consistent with their 'knowledge-based' view of intelligence. This view minimizes the evidence on *g*'s heritability and portrays the *g* factor mostly as a cultural artefact created by Western schools teaching some skills and knowledge rather than others, presumably to some students and not others (Gottfredson, in press a).

Tacit Knowledge

Sternberg et al.'s (2000) emphasis on distinct forms of knowledge leads directly to the most important construct in their measurement programme – tacit knowledge. In their view, the general intelligence factor *g* reflects the 'facile acquisition of formal *academic* knowledge' whereas practical intelligence reflects the 'facile acquisition and use of *tacit* knowledge' (Sternberg et al., 1995: 916, emphasis added).

Tacit knowledge is 'experience-based knowledge relevant to solving practical problems' (Sternberg et al., 2000: 104–105). It is therefore highly context-specific procedural knowledge: 'tacit knowledge is always wedded to particular uses in particular situations or in classes of situations' (Sternberg et al., 1995: 917). It is acquired on one's own with little support from the social environment, is often not verbalized, and is useful in attaining personal goals. They describe it more colloquially as 'practical know-how', 'knowing the ropes', and 'street smarts'.

Because tacit knowledge is the *untaught* fraction of procedural or 'practical' expertise, it would seem to be much narrower than the construct it is meant to measure – the 'ability to solve real-world everyday problems [and] ... adapt to, shape, and select everyday environments'. Sternberg et al. (2000: xi) justify focusing their measurement programme on tacit knowledge by stating that it is 'one particularly important aspect' of practical intelligence. They do not say what the other aspects might be.

ASSESSMENT INSTRUMENTS

Tests of Tacit Knowledge

Because tacit knowledge is highly specific, separate tests of tacit knowledge are required for every setting. Sternberg and his colleagues have focused on tacit knowledge for jobs, and have developed inventories for academic psychology, management, sales, and three levels of Army officers. The test of Tacit Knowledge in Management (TKIM) was once available from the Psychological Corporation, but no tacit knowledge test is currently available commercially. See Wagner (1987) for examples of items on the academic psychology test and early versions of the management test, appendices in

Sternberg et al. (2000) for copies of the sales (TKIS) and most recent management test (TKIM), and Hedlund et al. (1998) for the tests of military leadership at three levels (TKML-platoon leader, TKML-company commander, and TKML-battalion commander).

Sternberg et al. (2000) mention only one tacit knowledge test for a non-work setting: a test for Kenyan children's knowledge of herbal remedies (Sternberg, Nokes, Geissler, Prince, Okatcha, Bundy & Grigorenko, 2001). There are no criterion-related studies with this test.

Tacit job knowledge tests generally pose 7–19 problem-solving scenarios that job incumbents have verified as important in their occupation (platoon leader and so on). Each scenario lists 6–16 potential actions to take, all of which respondents rate on a 7- or 9-point scale for either quality or importance. For example, one scenario on the inventory for academic psychology asks respondents to rank the likely effectiveness of different strategies for '[becoming] one of the top people in your field and [getting] tenure in your department' – for example, 'improve ... your teaching', 'write a grant proposal', and so on (Wagner & Sternberg, 1985: 440). Each tacit knowledge test generally has several subscales: for example, the academic psychology test contains scales on managing self, others, and career.

Only the sales test is scored for accuracy of response. The others are scored for similarity of respondents' answers to those of incumbents designated as experts. Tacit knowledge tests are therefore scored more like interest inventories than ability tests.

Internal consistency reliabilities are reported for about half the studies (see Table 1). Of those reported, the alphas range from 0.66 to 0.85 for total scores.

Sternberg Triarchic Ability Test (STAT)

Sternberg has also developed a test intended to measure academic, creative, and practical abilities, primarily in academic settings (e.g. Sternberg, Castejon, Prieto, Hautamaki & Grigorenko, in press). I will not discuss it here because it is currently being revised, perhaps because its three scales all appear to measure *g* more than anything else (Brody, in press).

RESEARCH

Table 1 lists all six criterion-related studies that Sternberg et al. (2000) summarize, plus one other (Colonia-Willner, 1998) they bring up only in the context of mental ageing. As shown in Table 1, the seven studies include 12 samples of workers in five moderately high-level occupations.

General Factor of Practical Intelligence

The way to determine whether a general factor of practical intelligence exists is to factor analyse a large diverse set of tacit knowledge tests. Sternberg and his colleagues lack such data because they have administered two tacit knowledge tests to only three samples of Army officers and one sample of Yale undergraduates. Sternberg et al. (2000) nonetheless concluded that tacit knowledge reflects a 'domain-general' ability, based largely on the finding that performance on the psychology and management tests correlated 0.58 in the sample of 66 Yale undergraduates (Wagner, 1987). Table 1 shows that the management and leadership tests correlated only −0.06, 0.32, and 0.36 in the three samples of Army officers. Sternberg et al. (2000) interpreted the latter results as evidence for the 'domain-*specificity*' of tacit knowledge tests.

Independence of Tacit Knowledge and *g*

Because there is no evidence for a general factor of practical intelligence, there can be no evidence yet that any such factor is independent of *g*. The Sternberg team bases its claim for the independence of practical intelligence from *g* on the low correlations of *individual* tacit knowledge tests with scores on some IQ test or subscale (e.g. Shipley Institute for Living Scale; Concept Mastery Test Analogies Subscale). Table 1 presents the correlations for workers (see Gottfredson, in press a, for the results for students). The relevant correlations from the four samples are low (0.09 to 0.30), but interpretation is clouded by the fact that the average IQ in these samples was highly restricted in range (for example, the IQ of the 45 business managers in leadership training averaged IQ 120, which is the 90th percentile).

Table 1. Criterion-related studies of job tacit knowledge

Publication/report	Sample	*N*	Test of tacit knowledge	Alpha reliability	Job outcome criteria	*N*-weighted *r*'s:		
						Criteria &		IQ &
						TK	IQ	TK
Wagner & Sternberg (1985)	Psychology professors (USA)	54	Psychology	0.77	*N* of publications, citations, conferences attended, papers presented; dept. scholarly rank	0.29	–	–
	Business managers (USA)	54	Management	0.68	Level of company prestige, salary, job title; *N* of employees supervised	0.26	–	–
	Bank managers (USA)	29	Management	?	% salary increase; rated performance in personnel, new business, policy, and overall	0.42	–	–
Wagner (1987)	Psychology professors (USA)	91	Psychology	≥0.74	*N* of publications, citations, papers presented; dept. scholarly rank	0.35	–	–
	Business managers (USA)	64	Management	≥0.79	Level of company prestige, salary	0.13	–	–
Wagner & Sternberg (1990)	Business managers (USA)	45	Management	?	2 small-group managerial simulations	0.61	0.38	0.14
Williams & Sternberg (undated)	Business managers (USA)	?	Management	?	Level of position, compensation, age-controlled compensation, satisfaction	0.34	–	–
Wagner et al. (1999)	Life insurance salespeople (USA)	48	Sales	0.82[a]	Sales volume and premiums in two years; quality awards	0.22	–	–
Colonia-Willner (1998)	Bank managers (Brazil)	157	Management	0.85	Salary, *N* of people supervised, rated performance; composite index	0.06	−0.04	0.30
Hedlund et al. (1998)	Platoon leaders (US Army)	368	Platoon leadership	0.69	3 peer and 3 supervisor ratings of leadership	0.10	0.05	0.10
			Management	?	Same	0.02		0.09
	Company commanders (US Army)	163	Company leadership	0.76	3 subordinate, 3 peer, and 3 supervisor ratings of leadership	0.09	−0.09	0.19
			Management	?	Same	−0.09		0.15
	Battalion commanders (US Army)	31	Battalion leadership	0.66	3 subordinate and 3 peer ratings of leadership	0.10	0.13	0.09
			Management	?	Same	0.13		0.16

? = Data not reported.
– = Data not collected.
[a]Data include 48 students.
Note: All tacit knowledge scales have been reflected here so that better scores (smaller deviations from the experts) yield positive correlations.

Criterion-Related Validity of Tacit Knowledge

Table 1 summarizes the criterion-related validities for total scores on the tacit knowledge tests. All are concurrent validities and none is corrected for unreliability or restriction in range. The table reveals a diverse mix of job outcome criteria, ranging from careerist (e.g. salary, job title, job satisfaction) to quality of performance on the job (e.g. sales awards, rated leadership), the former being of interest mostly to workers and the latter mostly to employers. The mean criterion correlations are substantial – generally around 0.3 – for the five civilian studies that Sternberg et al. (2000) highlight (the first five in Table 1), although the results for specific criteria (not shown) often do not replicate across parallel studies (Gottfredson, in press a). More importantly, the criterion validities are near zero in the two studies whose results Sternberg et al. (2000) either do not report (0.06; Colonia-Willner, 1998) or say little about (−0.09, 0.02, 0.09; Hedlund et al., 1998). The former is the largest civilian study, and the latter is the largest, most carefully executed, and least careerist-oriented study of the entire set of seven.

Criterion-Related Validity of Tacit Knowledge versus IQ

Sternberg et al. (2000) base their claim that practical intelligence is arguably a better predictor 'of success' on two facts. The first is that tacit knowledge correlated 0.61 but IQ only 0.38 with (simulated) performance in their study of 45 managers in leadership training. They do not mention the negative results from the Colonia-Willner (1998) study – 0.06 for tacit knowledge versus −0.04 for IQ. Again, they say next to nothing about the results from the unpublished study of Army officers, where mean criterion correlations were low (−0.09 to 0.13) and virtually identical for both IQ and tacit knowledge. The second fact to which they appeal is that the criterion correlations they highlight for tacit knowledge are about twice as large as the average correlation for IQ they say is reported in the job performance literature. As detailed elsewhere, however, they grossly overstated their own results while grossly understating the field's estimates for *g*. A careful accounting shows exactly the opposite pattern (Gottfredson, in press a).

Summary

No assessment has yet been shown to measure a general factor of practical intelligence. Tests of tacit knowledge for specific occupations have yielded moderate correlations with outcome criteria in six samples of incumbents but not in six others. Tests of *g*, which are not targeted to any occupation, correlated equally well (or poorly) with performance outcomes in four samples, worse in one, and better in a sixth sample – all of which were restricted in range on intelligence. There are no data on the value of tacit knowledge in low- to moderate-difficulty occupations or in non-work settings.

FUTURE PERSPECTIVES AND CONCLUSIONS

Considerably more research will be needed to establish whether practical intelligence is a viable construct. Should a general factor of practical intelligence be identified in the future, tests measuring it must be factor analysed together with traditional mental tests in order to determine whether the practical intelligence factor is, in fact, independent of the *g* factor and, if not, where it fits into the *g*-topped hierarchical model of human intelligence.

Although Sternberg and his colleagues describe tacit knowledge as an important aspect of practical intelligence, it seems unlikely that tacit knowledge tests could individually be good measures of any general ability factor because, by design, each is highly setting-specific and experience-based. IQ tests succeed in measuring a context- and content-free general ability by stripping test items of all need for specialized knowledge and experience. Tacit knowledge tests do just the opposite.

The very specificity that makes tacit knowledge tests poor candidates for measuring a general ability might make them good candidates for measuring important but neglected forms of specialized knowledge. Because their items generally have no objectively correct answers, however, research needs to verify that the tests actually do measure knowledge rather than some non-intellectual attribute (say, a zeal for self-promotion).

PREDICTION (GENERAL)

INTRODUCTION

If prediction is a statement about an unknown and uncertain event (Ledolter, 1986) then many activities in the domain of psychological assessment can be characterized and discussed from this perspective. Thus, a nosological classification usually has implications for the values of variables not used for this classification, and leads to expectations of future behaviour of a client. Deciding on an intervention is related to a prediction of success; the selection and use of assessment instruments is equivalent to the choice of predictors.

Assessors rarely face the task to evaluate predictions derived from a well established theory. Usually, to test their assumptions they have to resort to routine statistical prediction procedures like regression and discriminant analysis. Since they quite often cannot refer to a large number of observations on the same person over a long period of time, they cannot use methods of extrapolation in time series called forecasting. Instead, they have to refer to only a few observations on many persons over a short period of time and to consider the single case to be assessed in relation to characteristics of samples of persons.

COMPONENTS OF THE PREDICTION TASK

Criteria

Predicting criteria on the basis of predictors is one of the most important activities in psychological assessment (*cf.* Wiggins, 1973). Criteria in psychological assessment are, in most cases, criteria of success which refer to future behaviour of the persons concerned in situations that are different from those in which the original assessment, i.e. the assessment of the predictors, takes place. Typical problems dealt with in psychological assessment are selecting treatments and interventions, recommending programmes of training, education and exercise. Parents may ask for help when selecting an educational career for their children, adolescents when trying to overcome difficulties at university. In each case, success is the crucial issue: success of a treatment or intervention; success of a training programme, an educational measure, or an exercise. Will the educational career of the child chosen by the parents be successful? Will the adolescent successfully overcome the difficulties at university when a certain kind of intervention is applied? etc.

The *reliability* of a criterion determines an upper bound to its predictability: an unreliable criterion cannot be predicted. Quite often, the instability of replications is due to a lack of replicability of the criterion.

Selection and Characterization of Predictors

The optimum is to derive predictors from a theory which links constructs on the predictor side to constructs on the criterion side – if such a theory exists. Given a set of predictors, reliability of each one is of utmost concern. Some models like linear regression assume that the predictors are measured without error. If the scale level of a variable is high, this variable in general is better suited as a predictor because the higher scale level indicates that the variable may provide more information. Then chances are better to have information available which is useful for prediction.

One reason why more than one predictor should be used is the possibly complex nature of the criterion. If it is composed out of several components, predictors may be related to different subsets of these components. This should lead to a relatively low correlation between predictors. On the other hand, within some prediction models, the predictors may serve like items in classical test theory to increase the reliability of the overall score.

Combination Rules

We may order the combination rules by their *degree of analyticity*, i.e. the degree to which they decompose a pattern or profile of values observed over all predictors for a specific person. Very compact in this respect is Configuration Frequency Analysis (CFA) by Krauth and Lienert (1973), especially in its form as Prediction Configural Frequency Analysis. This model predicts qualitative criteria by means of qualitative predictors. CFA decides for a pattern as a whole whether it constitutes a predictive type; if the occurrence frequency is not significant, the pattern is dismissed as without predictive power.

Classical regression and discriminant analysis show the highest degree of analyticity by treating each variable of the pattern set separately as a single predictor. It may possibly be replaced or not be considered from the very beginning, or even to be eliminated without replacement by a similar one. Somewhere between the extremes of CFA and variants of the general linear model, Feature Pattern Analysis (FPA) is placed (Feger, 1994). This model lets the data determine whether contingencies of the first, second etc. order are needed to reproduce the data sufficiently well.

Another fundamental distinction between prediction rules is introduced by Coombs (1964). He distinguishes between *compensatory*, *conjunctive*,

and *disjunctive rules* in the respective (multidimensional) composition models. In a compensatory rule the same criterion value may be achieved if 'the shortage in one attribute may compensate with an excess of another attribute'. Compensation may occur for weighted or unweighted values, and within an additive, multiplicative or more complex function. A conjunctive rule demands that every variable shows a predefined minimum value to achieve a positive criterion value. In contrast, disjunctive composition 'is that in which successful performance on a task requires a certain minimum on *any one* of the relevant dimensions' (Coombs, 1964: 247).

With the small samples often used in psychology, weighting systems such as the β-weights in regression analysis may be difficult to pass the test of cross-validation. Equal weights are sometimes less affected by the peculiarities of the sample used. Once relevant variables are included in the prediction equation, the specific method of predictor weighting may be unimportant (*cf.* Dawes, 1979).

PREDICTION MODELS

Actuarial Systems

Predictors and criteria may be dichotomous or polytomous. Their relationship quite often is expressed in the form of a *contingency* or *actuarial table* with conditional probabilities as elements, and a statement derived from such a table may be, for example, 'Given the marital status "divorced" and the sex "male", the probability that an individual will achieve a given criterion status is higher than 0.50.' For the statistical background of actuarial systems see von Eye (1991). In psychological assessment, systems for actuarial prediction were, first and foremost, developed on the basis of the MMPI. Especially in the 1970s, several competing actuarial systems built upon MMPI-scales as predictors. For an introduction to the systems of Gilberstadt and Duker, of Marks and Seeman, and of Sines see Wiggins (1973).

Regression

Regression in its most popular form, i.e. multiple linear regression, combines additively several weighted predictors $X_1, \ldots, X_k$ to derive a predicted value Y'. A quadratic loss function is used to determine the weights β_0, $\beta_1, \ldots, \beta_k$ and thus to minimize the expectation $E[(Y - Y')]$, with Y as the criterion. The fundamental equation may be written as

$$Y \cong Y' = \beta_0 + \beta_1 X_1, \ldots, \beta_k X_k.$$

Predictors and the criterion are assumed to be interval scaled, and the measurement of the predictors is assumed to be free from errors. Whether the estimates of the weights are optimal depends on the quality, especially the size and representativeness, of the sample used. A cross-validation is indicated in general.

The basic ideas of classical regression have since the 1950s been supplemented by the concepts of moderator variable and suppressor variable. A *moderator variable* (Saunders, 1956) divides the population into homogeneous subgroups like women and men. Within every subgroup the predictors–criterion relations are valid to a different degree or even in a different kind. This can be expressed by extending the regression equation by a *linear joint function* with X_k as the hypothesized moderator:

$$Y \cong Y' = \beta_0 + \beta_1 X_1, \ldots, \beta_k X_k + \beta_l X_i X_k.$$

The last term of this equation is also called the multiplicative model.

Instead of finding an optimal prediction for all persons simultaneously – as regression analysis intends – Ghiselli (1956) differentiates among persons. Some are, at least in terms of their deviation from a regression line, more predictable than others. Knowing in advance a (moderator) variable which correlates with predictability would allow very accurate predictions for the more predictable persons, and perhaps lead to an assignment of the less predictable persons to a different prediction procedure.

A *suppressor variable* is defined by a low correlation with the criterion but a high correlation with some other predictor(s). The idea is that a suppressor variable correlates with variability in the predictors that does not contribute to the relationship between criterion and predictor. Typical suppressor variables in psychological assessment are response sets.

In psychology, the assumptions of multivariate linear regression rarely are satisfied, neither the interval scale level, nor the error-free measurement of the predictors, nor the multivariate normal distribution of the values of these variables. Furthermore, some assumptions like the additive combination of the predictors are in conflict with the researcher's knowledge of the substantive area. Therefore, several alternatives to classical regression have been developed (*cf.* Myers, 1990) which should get much more attention in psychological assessment than they got in the past.

Discriminant Analysis

Discriminant analysis replaces the continuous criterion of regression analysis by a polytomous criterion. One starts the analysis with a set of observations indicating which vectors of predictor values co-occur with a specific group membership. If the criterion comprises two groups, the forms of the general linear model of the two approaches are identical. For more than two criterion groups, more than one discriminant function exists in general. These functions are so constructed that differences between the groups are as large as possible, and differences within the groups as small as possible (Krauth, 1983a).

The assumptions of this well-known variant of the general linear model are the same as with regression analysis, plus some specifics, to mention interval scale level, multivariate normality of the predictors, correct classification of the base samples and equal covariances of the different groups. Since some of these assumptions are usually violated in psychological applications, alternatives have been proposed, e.g. the construction of non-parametric classification rules, the use of qualitative predictors, or predictors with ordered categories (*cf.* McLachlan, 1992).

EVALUATION OF PREDICTION

A first step of an evaluation could be a thorough test of the model fit because the trust in the model and the estimation of its predictive success depends on the appropriateness of this model. There exists ample knowledge on how to evaluate a regression study, e.g. the graphical approach by Cook and Weisberg (1994) or the sensitivity analysis in linear regression by Chatterjee and Hadi (1988). More specifically, the evaluation of a predictive system '... concerns the optimal selection of predictors, the construction of suited measures of the prediction error and the predictive power, the robustness of predictions, the comparison of clinical with statistical predictions, the evaluation by cross-validation, etc.' (Krauth, 1983b 143). A prelude to these sophisticated measures may be the test whether the system predicts better than chance, and – if a good estimate is available – better than base rate.

Cross-validation is a necessity. The *cross-validity* of a prediction system is usually determined by splitting the total available sample into two subsamples. Then the regression equation computed in one subsample (the estimation sample) is applied to the data of the other subsample, and the predictive success in this second, the cross-validation sample, is taken as an indicator of the system's validity.

FUTURE PERSPECTIVES AND CONCLUSIONS

As shown in this entry, there exists a large qualitative variety of prediction methods for psychological assessment. One may expect that – as these procedures become better known and convincing pioneer applications are published – the various tasks of prediction will be solved in better agreement between the data at hand and the prediction model to be used. As an example, the latest version of SPSS provides almost a dozen models of regression analysis, including one with optimal scaling. Conceptualizing prediction in psychological assessment as decision-making under uncertainty may lead to probabilistic models, especially to Bayesian analyses of dynamic models (for a sophisticated introduction, see West & Harrison, 1989). Their broad use in psychological assessment may be seen in the future.

RELATED ENTRY

Prediction: Clinical vs. Statistical

PREDICTION: CLINICAL VS. STATISTICAL

INTRODUCTION

In psychological assessment, an important step in the process of assessment is the prediction of criteria on the basis of assessment data, the so-called predictors. The processing of assessment data, which yields a prognosis, can follow two different methods of data combination: the *statistical method* and the *clinical method*. In the case of the statistical method, the combination of predictors is determined entirely on the basis of known empirical relationships between the predictors and the criteria; that is, on *intersubjective knowledge* as it arises from well-designed empirical investigations. In the case of the clinical method, no such empirical relationships are available or used; the combination of predictors is done in an 'intuitive' way based upon the *subjective knowledge* of the assessor which arises from his or her personal and professional experience.

The term 'clinical' in clinical prediction should not be misunderstood. It does not mean that this method of data combination occurs only in clinical psychology. The reasons for the choice of this term are historical and not systematic ones; and they reflect a long-standing controversy in psychological assessment between the advocates of intersubjective ways of information processing on the one side and the advocates of subjective ways on the other. Wiggins (1973) gives the best available reconstruction of this controversy, which has its origin in clinical psychology, but is in no way confined to this field of application of psychological assessment. Wherever, inside or outside of clinical psychology, criteria are predicted (only) on the basis of subjective knowledge, it is an instance of clinical prediction. And wherever criteria are predicted (only) on the basis of well-confirmed empirical knowledge, it is an instance of statistical prediction, regardless of the concrete statistical procedures used, e.g.

actuarial tables, or linear or non-linear regression equations.

THEORETICAL ISSUES

The most important issue in the controversy between advocates of clinical and statistical methods of data combination was and is the question: 'Which method to combine assessment data in the course of predicting criteria is better: the clinical or the statistical one?' This issue can be treated from a theoretical and an empirical point of view. Meehl (1954) considered both points in his famous book *Clinical versus Statistical Prediction: A Theoretical Analysis and a Review of the Evidence*. From a theoretical point of view, the central question is: 'Are there any a priori reasons why one method of data combination should be superior to the other?'

At the beginning of the controversy, the adherents to the statistical approach thought that their method must be better than the clinical one, because their method could be considered as mathematically optimal. The regression weights in a linear regression equation, for example, are determined in such a way that the (sum of squared) deviations of the observed criterion scores from the predicted ones are minimized. Therefore, it is impossible – that was the argument – that clinical prediction could beat statistical prediction. Only in those highly improbable cases where the intuitive estimation of regression weights by an assessor who uses the clinical method comes to the same results as the application of the statistical method will the clinical method be equal to the statistical method; in all other cases, it will be inferior.

Meehl pointed out that this argument is not really convincing. It mingles two contexts, which should be kept apart: the *context of discovery* and the *context of justification* of a prediction. The context of discovery refers to how a prediction comes about; the context of justification refers to the validity or accuracy of a prediction independent from its origin. The advocates of the statistical method who preferred linear regression methods presupposed in their argumentation that there is only one way to come to a prediction: the explicit (in the case of statistical prediction) or implicit (in the case of clinical prediction) computation and application of regression equations. Meehl showed that this presupposition is wrong. There are other ways, which could be utilized by the advocates of the clinical method.

Imagine an assessor who does not base his or her predictions on characteristics of samples of persons but who invents an *idiographic theory* for each single case to be assessed and infers the to be predicted criterion scores of the respective person from this theory and appropriate assessment data. The case-related invention of structural-dynamic hypotheses, which make up an idiographic theory, is a quite different kind of activity compared to the computation of a linear regression equation in the case of the statistical method. This shows that there are alternatives to the statistical method in the context of discovery, which might be utilized by the advocates of the clinical method of prediction. And it is possible, from a theoretical point of view, that predictions based upon idiographic theories are more accurate and valid than predictions based upon the statistical method. Statistical regression methods, for example, build upon sample data and cannot avoid more or less pronounced deviations of the individual criterion scores from the average scores represented by the regression line. If the assessor should be successful in his or her efforts to construct accurate case-related idiographic theories, he or she might be able to hit the individual criterion scores much better than any statistical method of prediction.

Meehl (1954) made it very clear that this is, so far, only a theoretical discussion. Whether the alternative ways of data combination he considered are really utilized in clinical prediction, and whether they lead to predictions that are superior to those made within the statistical approach, are completely empirical questions.

EMPIRICAL RESULTS

Clinical Prediction

The most important approach to the study of the clinical prediction process makes use of Brunswik's lens model. This model allows a *paramorphic representation* of clinical prediction, i.e. a representation based upon an input–output analysis of clinical prediction. An adequate paramorphic model of an assessor who uses the clinical method of data combination in the course of predicting

a criterion is a model that yields more or less the same criterion scores as those predicted by the assessor when both, assessor and his or her model, base their predictions on the same input data (*cf.* Wiggins, 1973, for more details).

Various models have been tried out in investigations of this issue. The simplest one is, of course, the *linear regression model*. Other models are the result of an enrichment of this simple model by quadratic, cubic, or other even more complex terms, which turn the linear model into *non-linear regression models*. One of the more recent proposals of non-linear models of clinical prediction are the sophisticated *scatter models* of Ganzach (1995). His study, as well as all other studies of this issue done before, shows the remarkable success of the simple linear regression model in any attempt to represent the clinical prediction process in a paramorphic way. More complex non-linear models might be better in some cases, but the fit for these models is only slightly better than for the simple linear model.

This does not mean that the assumption made by the early advocates of the statistical method that the assessor who follows the clinical method of data combination implicitly computes and applies a linear regression equation when predicting criterion scores is already well proven, but this assumption has become much more plausible than it was in those days.

Comparison of Clinical and Statistical Prediction

In situations in which a criterion is to be predicted on the basis of a set of predictors and data about the actual criterion scores are available, clinical and statistical methods of data combination can be compared. The validity of the clinical method, i.e. the correlation between the clinically predicted and the actual criterion scores, is compared with the validity of the statistical method, i.e. the correlation between the statistically predicted and the actual criterion scores. Three outcomes of such a comparison are possible: (1) the clinical method is superior, (2) the statistical method is superior, (3) both methods are equally effective. Meehl (1954) in the empirical part of his famous book reviewed some 16 to 20 studies that were relevant to the issue and found 11 studies in which the statistical method was superior to the clinical method, 8 studies in which both methods were equally effective, and 1 study in which the clinical methods seemed to be superior. Later, it turned out that the last mentioned study was based on a faulty statistical analysis. It had to be counted as a tie in later tabulations. In 1965, after a lot of empirical work, the balance was even more impressive: in 33 studies the statistical method was superior, in 17 studies equally efficient, and only in 1 study inferior to the clinical method (Meehl, 1965). Again, this study had to be reclassified as a tie after further inspection.

Only one year later, Sawyer (1966) published a reanalysis of these data introducing another important aspect. Whereas Meehl considered only the combination of assessment data, Sawyer added the collection of assessment data as another aspect. He differentiated between *judgemental* and *mechanical* modes of data collection with a free interview as an example of the judgemental and a standardized test as an example of the mechanical mode. The analysis of the empirical studies of clinical versus statistical prediction done so far showed that four cases occur: (1) studies with assessment data only collected in the judgemental mode, (2) studies with assessment data only collected in the mechanical mode, (3) studies with assessment data collected in both modes, (4) studies with assessment data collected either in the judgemental or in the mechanical or in both modes. Combining this differentiation with the clinical versus statistical differentiation with regard to the aspect of data combination, Sawyer obtained an eight-fold classification system of prediction methods. Instead of comparing only the statistical method with the clinical method, Sawyer could compare the eight prediction methods with one another. Nevertheless, the results confirmed Meehl's conclusion: for each mode of data collection, the statistical method of data combination turned out to be superior to the clinical method. The best results were obtained with a prediction method called *mechanical composite*, i.e. the statistical combination of judgemental and mechanical data.

Comparison of Clinical and Mechanical Prediction

Grove et al. (2000) in their most recent meta-analysis of prediction studies introduced another differentiation: clinical versus mechanical

prediction. The term 'clinical prediction' is used in the somewhat narrower sense of 'prediction by an assessor without a precise specification of the way the assessment data are combined'. Automated clinical prediction, prediction by an expert system without an empirical validation of the system, and prediction by applying the linear or non-linear paramorphic model of an assessor who used the clinical method (*cf.* Wiggins, 1973) are no longer instances of clinical prediction, but instances of mechanical prediction. The decisive feature of *mechanical prediction* is that the data combination follows precisely formulated rules and is 100% reproducible in its results. A successful empirical test of the combination rules, the decisive feature of statistical prediction, is no longer required.

Even under these weaker conditions, the meta-analysis of 136 studies showed that, on an average, the mechanical prediction techniques were about 10% more accurate than clinical predictions. In many cases, they substantially outperformed clinical predictions. Only in a few studies were clinical prediction methods substantially more accurate (Grove et al., 2000: 19).

FUTURE PERSPECTIVES AND CONCLUSIONS

After decades of research, the question 'Which method to combine assessment data in the course of predicting criteria is better: the clinical or the statistical one?' can be answered in an unequivocal way: the statistical method (*cf.* Meehl, 1986). And if a paramorphic model is wanted which helps to understand what is going on in clinical prediction, the simple linear regression equation is still an excellent choice. These conclusions may disappoint persons who tend to mystify 'intuitive' processes wherever they occur. In psychological assessment as in other areas of psychology, it is time to break the spell of these myths (*cf.* Dawes, 1994). That means, in the case of psychological assessment, that the assessor should construe the assessment process as a well-ordered, regulated process that has to refer to the knowledge base, provided by psychology as a science, whenever possible. If there were well-confirmed empirical results concerning the relation between predictors and criteria available, not to use them in a prediction task would be a serious lapse. To avoid errors like this one in the course of an assessment process, the assessor should observe the Guidelines for the Assessment Process already proposed by a Task Force of the European Association of Psychological Assessment (*cf.* Fernandez-Ballesteros et al., 2001).

PREDICTION (GENERAL), ASSESSMENT PROCESS, INTELLIGENCE ASSESSMENT (GENERAL), THEORETICAL PERSPECTIVE: COGNITIVE

PRE-SCHOOL CHILDREN

INTRODUCTION

The purpose of assessment with pre-school children typically is two-fold: the first focus is on screening groups of children and the second is on programme planning for identified children, both with the overall goal of improving developmental outcomes. Developmental progress is a primary concern in the assessment of young children and includes a focus on cognitive, motor, and social development. While assessment of specific areas of concern are important, our focus here is on a general area of concern relevant for the broader population of pre-schoolers – the skills and knowledge essential to early school success: specifically, basic developmental skills and social behaviour. Assessment of these skills can be conducted at the screening level and at the programme planning level.

BASIC SKILLS AND KNOWLEDGE

Contemporary approaches to assessment with pre-school children emphasize the use of a convergent model in which assessment is a process of collecting information in a variety of ways, from a variety of sources, and in reference to a variety of domains (Bagnato, Neisworth & Munson, 1997). Global assessment typically involves a broad range of basic skills and knowledge, promoting a comprehensive evaluation of a child's functioning. Assessments may be conducted through observation, direct assessment, and informant reports. The three global assessment tools reviewed here demonstrate adequate technical characteristics, promote family involvement, and meet the unique needs of assessment with young children (see Table 1).

American Guidance Service's Early Screening Profiles

American Guidance Service's Early Screening Profiles (Harrison et al., 1990) is an individually administered screening tool intended to identify children who may warrant further assessment. While not specifically linked to a curriculum, the skills and knowledge assessed are consistent with basic concepts essential to early school success. The tool consists of three profile measures and four surveys. Some measures are administered directly to the child; others are questionnaires completed by parents and/or teachers. Administration of component measures is flexible and determined by the assessment purpose.

The Cognitive/Language Profile consists of four sub-tests: Verbal Concepts, Visual Discrimination, Logical Relations, and Basic School Skills. The Motor Profile assesses gross and fine motor skills. The Self Help/Social Profile provides a measure of the child's communication, daily living skills, socialization, and motor skills. The Articulation Survey assesses quality of speech production. The Home Survey and the Health History Survey provide information about the child's home environment, parent–child interactions, and health problems. Finally, the Behaviour Survey rates a child's behaviour during the test administration.

The Early Screening Profiles provide two levels of scoring. The first level yields six 'screening indexes' and three descriptive categories. Screening index scores are matched to a normative distribution. Professional judgement is used to determine criteria for referral based on Screening Indices. Level II scoring consists of standard scores, percentile ranks, and age equivalents and allows for a range of interpretations for broad sub-scales and total scale as well as for more detailed analysis of patterns.

Bracken Basic Concept Scale – Revised (BBCS-R)

The Bracken Basic Concept Scale – Revised, BBCS-R (Bracken, 1998), is an individually administered, norm-referenced tool that measures foundational educational concepts and receptive language.

Table 1. Pre-school assessment tools

Assessment tool	Purposes	Age/focus group	Domain/content	Of note
Assessment, Evaluation, and Programming System	Assessment, programme planning, progress monitoring, evaluation	Children of ages 3–6 at risk for or presenting with developmental disabilities	Fine motor, gross motor, adaptive, cognitive, social-communication, and social	Uses curriculum-embedded naturalistic assessment and activity-based intervention approach. Strong family component
AGS Early Screening Profiles	Screening	Children of ages 2.0–6.11	Cognitive/language, motor, self-help/social, articulation, home, health, and behaviour	Includes family component for convergent approach
Bracken Basic Concept Scale – Revised	Speech–language assessment, cognitive screening, school readiness screening, curriculum-based assessment	Children of ages 2.6 to 8.0	Colours, letters, numbers–counting, sizes, comparisons, shapes, direction–position, self–social awareness, texture–material, quantity, and time–sequence	Has Spanish version for criterion referenced assessment only. Links directly to the Bracken Concept Development Program. Assesses receptive language only
Early Screening Project	Screening, programme planning, and evaluation	Children of ages 3–5 in a group setting	Adaptive, maladaptive, aggressive, and social interaction behaviour	Multi-gated procedure that includes direct observation and parent ratings. Includes assessment of internalizing behaviours.
Preschool and Kindergarten Behaviour Scales	Screening, identification, assessment, and programme planning and evaluation	Children of ages 3.0–6.0	Social skills, problem behaviour	Includes parent form for parallel assessment. Normative comparison is not separated for boys and girls
Social Skills Rating System	Screening, identification, programme development	Children of ages 3.0–4.11	Social skills, problem behaviour	Includes parent form. Rates importance of behaviour as well as frequency. Links directly to intervention planning

Stated uses of the BBCS-R include speech–language assessment, cognitive screening, school readiness screening, curriculum-based assessment, and clinic and school research. The BBCS-R is directly linked to the Bracken Concept Development Program, increasing its utility as a criterion-referenced and curriculum-based measure.

The scale is comprised of 11 sub-tests: Colours, Letters, Numbers/Counting, Comparisons, Sizes, Shapes, Direction/Position, Self/Social Awareness, Texture/Material, Quantity, and Time/Sequence. The first six sub-tests comprise the School Readiness Composite, which can be administered alone as a screening measure. In each sub-test the child is asked to respond to a stimulus containing the correct response and several distractors by pointing to the correct response; no verbal responses are required. For example, in Texture/Material, the child is presented with four pictures and asked to indicate which one is cold. Administration of the BBCS-R is relatively brief and easy and can be completed in approximately 30 minutes.

The BBCS-R yields scaled and standard scores, percentile ranks, confidence intervals, classifications, and concept age equivalents. Classifications

are assigned to ranges of standard scores and scaled scores, representing a continuum from Very Advanced to Very Delayed. To facilitate programme planning, scores are used with a Parent/Teacher Conference Form and a Percent Mastery Table. The Percent Mastery information assists in identifying areas of weakness, targeting intervention where per cent mastery is low.

Assessment, Evaluation, and Programming System for Infants and Children (AEPS)

Assessment, Evaluation, and Programming System for Infants and Children, AEPS (Bricker, Pretti-Frontczak & Waddell, 1996), is dedicated to measurement and curriculum issues for children with or at risk of developing developmental disabilities. It is a curriculum-based assessment system intended to promote naturalistic assessment and intervention practices. Volumes 1 and 2 focus on children from birth to three years of age, Volumes 3 and 4 focus on children from three to six years of age.

Families are included in the assessment process through the Family Report and the Family Interest Survey. The report promotes parallel assessment between parents and teachers and the survey helps families to prioritize interests related to programming for their child. The Child Progress Record provides a flow chart depicting progress towards identified goals and objectives, a visual summary indicating areas of mastery and areas for continued intervention.

The AEPS can be used in the home or in a small group, is a centre-based programme and assesses six domains of development: (1) fine motor; (2) gross motor; (3) adaptive; (4) cognitive; (5) social communication; and (6) social. Assessment is curriculum embedded, conducted while the child is engaged in naturally occurring activities, and based on observation of authentic skills. Each domain contains a list of strands, goals, and objectives to guide assessment. For example, the Adaptive domain includes strands of eating, dressing, and personal hygiene. Items are scored on a 3-point system and qualifying notes indicate whether assistance was provided or modifications were made. Additionally, each record includes space for three assessments – a visual cue that assessment should be ongoing.

SOCIAL BEHAVIOUR

Social behaviour is particularly important as children enter group situations, or structured learning environments. As many as 50% of toddlers and pre-schoolers identified as difficult to manage by their parents have been shown to have continued difficulties when they enter school. A number of instruments evaluate social behaviour at a screening level with groups of children and at a more specific assessment level with individual children. Three tools are reviewed briefly. The first tool is primarily for screening purposes; the second and third tools are for more focused assessment and intervention planning.

Early Screening Project (ESP)

The Early Screening Project, ESP (Walker, Severson & Feil, 1995), is a multi-gated screening tool to identify young children at risk of developing externalizing and internalizing behaviour problems. It can be used also for programme eligibility determination, intervention planning, and evaluation of intervention outcomes. Although not linked directly to a curriculum, the behaviours of focus are consistent with general social skills goals and the manual provides references for appropriate social skills programmes.

The first two stages of the ESP rely on teacher judgement. Teachers rank children in a classroom on externalizing and internalizing dimensions of behaviour. Externalizing items include not 'listening to the teacher, disturbing others, being hyperactive' (p. 9). Internalizing items include 'low activity levels, not talking with other children, being shy, timid, and/or unassertive' (p. 10). Teachers then rate the top three identified children on measures of adaptive behaviour, maladaptive behaviour, aggressive behaviour, and social interactions.

The third stage of the ESP consists of direct observation and a parent questionnaire. Social Behaviour Observations conducted during free play or unstructured activities focus on antisocial behaviour, non-social behaviour, and pro-social behaviour. The Parent Questionnaire contains items adapted from forms used in Stage Two and asks parents to evaluate the extent to which their child exhibits adaptive and maladaptive behaviours.

Scoring of the ESP is relatively simple. Teacher ratings are added, yielding a score to be used in normative comparisons. 'At risk' status is determined separately for boys and girls for each measure through normative comparison. Scores also are converted to T-scores, % of population, and corresponding percentile score.

Preschool and Kindergarten Behaviour Scales (PKBS)

The Preschool and Kindergarten Behaviour Scales, PKBS (Merrell, 1994), is a norm referenced, standardized measure to assess social behaviour. The scales consist of social skills and problem behaviour. The social skills domain is divided into cooperation, interaction, and independence. The problem behaviour domain includes sub-scales of self-centred/explosive, attention problems/overactive, antisocial/aggressive, social withdrawal, and anxiety/somatic problems. The manual states the PKBS can be used for screening, classification, programme development, and research.

The PKBS consists of seventy-six items describing a child's social and problem behaviour. Social skills items include 'is cooperative, invites other children to play, plays independently'. Behaviour problem items include 'will not share, disrupts ongoing activities, is physically aggressive'. Individuals who have known the child for at least 3 months rate the child on each item. The scales can be used in a variety of settings by teachers, caregivers, and parents. Parents and early childhood professionals use the same form and normative structure, allowing for direct comparison of ratings across settings.

Scoring of the scales is brief and simple. Raw scores in each domain are summed and converted to standard scores, percentile ranks, and functional levels. Standard scores can be used in normative comparisons and are divided by age, but not gender. Functional levels for social skills range from high functioning to significant deficit. Levels for problem behaviour range from no problem to significant problem.

Social Skills Rating System (SSRS)

The Social Skills Rating System, SSRS (Gresham & Elliott, 1990), is an individually administered, standardized, norm referenced system for evaluating social skills, problem behaviour, and academic competence of children. The stated purpose of the SSRS is to screen and classify children suspected of having social problems and to assist in developing appropriate interventions. The pre-school version of the SSRS consists of the Parent Form, the Teacher Form, and the Assessment–Intervention Record (AIR), and assesses social skills and problem behaviours. Cooperation, assertion, responsibility, empathy, and self-control are included in the social skills domain; externalizing, internalizing, and hyperactive behaviours are included in the problem behaviour domain. Child behaviour is assessed through direct observation and experience with the child.

The Parent Form consists of 49 items. Parents rate the frequency of specific behaviours from 'never' to 'very often' and the importance of the behaviour from 'not important' to 'critical'. The Teacher Form is completed by a teacher who has known and observed the child for at least 2 months. The teacher is asked to rate the child on 40 items using the same frequency and importance scales as in the Parent Form. Both forms yield scores in the two primary domains and scores for sub-scales in each domain. The Assessment–Intervention Record (AIR) integrates information obtained from the Parent and Teacher forms, facilitating analysis of child behaviour and development of appropriate intervention. Frequency and importance information is used to prioritize skills and areas for intervention.

Scoring of the SSRS is completed by summing the raw scores within each sub-scale. Sub-scale raw scores are summed to yield a total domain score. Raw scores can be converted into standard scores, percentile ranks, and descriptive behaviour levels. Interpretation and comparison is completed separately for boys and girls.

FUTURE PERSPECTIVES AND CONCLUSIONS

Assessment of basic skills and knowledge and social behaviour in pre-schoolers is essential to efforts at prevention and early intervention as well as in efforts to promote early school success. Assessment should be convergent and use data from multiple sources to guide decision making for programme planning, and other types of educational decisions. It should be focused on

functional and authentic skills and knowledge, and it should be linked to intervention design and programme planning. Care should be exercised in choosing assessment tools to ensure that they are adequate for the intended purpose, demonstrate technical adequacy, and meet the needs of assessment with young children. These needs in particular include accurate screening of children in need of further assessment, accurate identification of children in need of special support programmes, clear linkages to intervention and education strategies, and sensitivity to progress and change over time.

PROBLEM SOLVING

INTRODUCTION

The question of how people solve problems has traditionally been one of the main areas of research in the psychology of thinking. Duncker (1945) defined a problem as occurring when a living creature has a goal but does not know how to achieve it – there is a 'barrier' to be overcome between the given state and the desired goal state. Dörner (1976) differentiated between various types of barriers in terms of whether or not the goal state on the one hand and the means to achieve it on the other are clear to the problem solver. On the basis of these different types of barriers, the four types of problems in Table 1 can be distinguished (the table includes at least one example for each type of problem).

Interpolation problems are well-defined problems, while the other types of problems are ill defined in the sense used by Simon (1973).

Problem solving research explores aspects such as the cognitive processes involved in problem solving, e.g. typical stages of problem solving, general or specific problem solving strategies (e.g. means–end analysis, Newell & Simon, 1972), typical errors (Greeno, 1978), and differences in the problem solving skills of experts and novices (e.g. Chi, Glaser & Rees, 1982). Research also focuses on the relation between problem solving skills and personality characteristics, as well as the relation between problem solving ability on the one hand and intelligence and knowledge on the other.

In the present entry, some of the tasks used in the context of problem solving assessment will be described, with particular emphasis being placed on complex problems embedded in computer-simulated scenarios.

Table 1. Four types of problems according to Dörner (1976). See the following text for the explanations of the examples given

Goal state	Means	
	Known	Unknown
Known	Interpolation problem Examples: chess; 'tower of Hanoi'; anagram tasks	Synthetic problem Example: 'radiation problem'
Unknown	Dialectic problem Example: producing as many different words as possible from a given set of letters	Dialectic and synthetic problem Example: 'Lohhausen'

PROBLEM SOLVING ASSESSMENT

The tasks used in problem solving assessment can be classified according to the four different types of barriers mentioned above. At the beginning of the twentieth century a group of German psychologists, the so called 'Gestalt' psychologists, first investigated problem solving using 'insight problems', where the solution – the overcoming of an interpolation barrier – was restricted to a few decisive steps. Examples include the radiation problem (rays converge to destroy a tumour without destroying the surrounding healthy tissue), the candle problem (supporting a candle on a door, using only the candle, a box of matches, and tacks: the solution required using the box as a platform to support the candle) and the water jug problem. In later research, problems required the application of several steps, with no single step being 'decisive'. Classic problem solving research focused primarily on 'transformation problems'. Problem solvers were presented with a clear given state, a clear goal state, and a precisely defined set of allowable transformations – the task thus again consisted in overcoming an interpolation barrier. The 'tower of Hanoi' is probably the most well-researched problem of this kind; the Chinese 'tangram' puzzle is an everyday example.

To give an example, one version of the 'tower of Hanoi' problem can be stated as follows (see Figure 1): there are three pegs and three rings, each with a different diameter. The goal is to move the stack of rings from the left peg to the right, with the restriction that a larger ring must never be moved on top of a smaller one. You are permitted to move only one ring at a time from one peg to another.

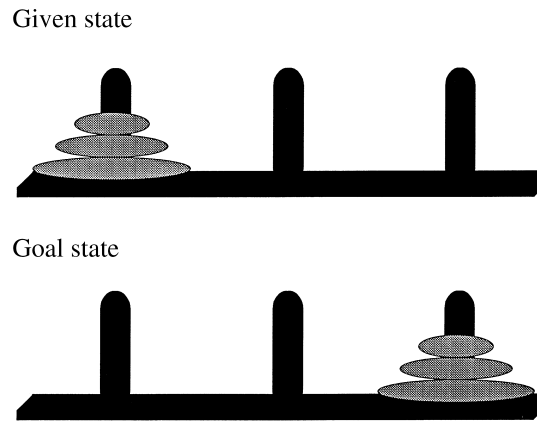

Figure 1. The 'tower of Hanoi' problem.

These kinds of 'move problems' or 'puzzle problems' have, in result-oriented form, found application in the context of practical diagnostics – the 'block design' and 'object assembly' subtests of the Wechsler Adult Intelligence Scale (WAIS), for instance.

Dialectic problems are used in contexts such as creativity research. A typical task with a dialectic barrier would, for example, involve producing as many different words as possible from a given set of letters.

Complex Problems

In the 1980s, divergent approaches were adopted in North American and European problem solving research. North American psychologists placed particular emphasis on domain-specific problems such as physics problems and algebra word problems, and on questions of expertise in specific domains such as chess.

In contrast, European research conducted over the past decades – particularly in England and Germany – has focused on problems with synthetic or synthetic-dialectic barriers rather than interpolation barriers. Such tasks have been termed 'complex' problems. The European approaches have been summarized in a volume edited by Frensch and Funke (1995). Reasons cited for the shift in focus to complex problem solving include the argument that interpolation problems have little in common with 'real life' problems. Above all, the fact that most interpolation problems are largely independent of (prior) knowledge was perceived as a serious limitation (Chi et al., 1982).

According to Dörner, Kreuzig, Reither and Stäudel (1983), complex problems can be described and simulated as systems of interconnected variables. These problems have the following characteristics:

- *Complexity:* Numerous aspects of a situation have to be taken into account at the same time.
- *Interconnectivity:* The various aspects of a situation are not independent and cannot, therefore, be independently influenced. Interconnectivity also includes the important role of feedback loops and side effects.
- *Dynamics:* Changes in the system conditions also occur without intervention from the problem solver.
- *Intransparency:* A situation is labelled intransparent when only a part of the relevant information is made available to the problem solver.
- *Polytely:* Sometimes the problem solver must simultaneously pursue multiple and even contradictory goals.

Computer-simulated scenarios are used as a way of translating such complex problems into an assessment context. Subjects have to run a city 'transportation system' (Broadbent, 1977) or manage a small factory. Funke (1991) provides an overview on the various scenarios. The most prominent example is the simulation called 'Lohhausen', where subjects have to act as the mayor of a small simulated town with the name 'Lohhausen' (Dörner et al., 1983). Subjects are able to manipulate taxes, influence production and sales policies of the city factory or the housing policy and so on. They are simply told to take care of the future prosperity of the town over a simulated ten year period within eight two-hour experimental sessions.

Advantages and Disadvantages of Using Computer-Based Scenarios for Diagnostic Purposes

In Europe, and especially in the German-speaking countries, computer-based scenarios are used as assessment tools in both research and practice. Some of the complex problem solving scenarios used in the context of personnel selection are presented by Funke (1995), and a discussion of the advantages and disadvantages of this form of application can be found in Funke (1998).

The main advantages of using computer-based scenarios as diagnostic tools are that the tasks (1) are highly motivating and (2) involve novel demands which (3) are deemed to have higher face validity than intelligence tests, and (4) that testtakers enjoy working with the simulations (see Kersting, 1999).

However, the diagnostic use of computer-based scenarios also entails serious difficulties that have yet to be overcome.

1. The central question of appropriate approaches to the operationalization of problem solving quality remains largely unanswered.
2. The reliability of the measurements obtained with some of the computer-based scenarios is less than satisfactory.
3. The existence of a task-independent and thus generalizable problem solving ability has not yet been substantiated. This indicates that the ability to direct the system is dependent not only on the skills of the problem solver him- or herself, but evidently also on the nature of the task in question.
4. The main problem is that of construct validity. It is still unclear which skills are actually measured by means of the computer-based scenarios. Either the measurement is interpreted as an indicator for an independent *ability construct* (as suggested by newly coined terms such as 'networked thinking', 'heuristic competence', 'operative intelligence', etc.), or the scenarios are regarded as a new *measurement method*

which, in a certain respect, is better able to measure established constructs such as intelligence than has previously been the case (e.g. in a more differentiated manner or with a higher level of acceptance). Beckmann and Guthke (1995) have summarized the European research dealing with the controversial relation between traditional measures of intelligence and problem solving skills.

5 Evidence for the criterion validity of the measures used is also urgently needed. Thus far, only a single study (Kersting, 1999) has directly compared the predictive criterion validity of computer-based scenarios with the validity of existing procedures deemed to have overlapping coverage.

FUTURE PERSPECTIVES

Significant progress in the domain of problem solving assessment cannot be expected until both the operationalization of problem solving quality and the psychometric quality of the diagnostic instruments have been improved. Above all, it is essential to classify the ability tapped by the performance measures within the existing nomological network. Studies are required in which sufficiently reliable measurements are implemented by means of *different* computer-based scenarios, and differentiated measures of intelligence are administered in sufficiently large samples. At the same time, tests of other theoretically relevant constructs such as knowledge also need to be administered. In investigations of this kind – for instance, the study conducted by Wittmann and Süß (1999) – it has emerged that the systematic variance captured by problem solving scenarios can be attributed to intelligence and prior knowledge, and that there is no empirical evidence for the existence of problem solving ability as an independent construct.

CONCLUSIONS

Tasks have been constructed with the objective of providing insights into problem solving behaviour since the times of Gestalt psychology. In recent decades, the computer has opened up new diagnostic possibilities to this effect. The new types of task are associated with new problems, however. For most problem solving tasks, further insights into aspects such as the reliable measurement of problem solving ability and construct and criterion validity are required before the tasks can be responsibly used in diagnostic practice.

PROJECTIVE TECHNIQUES

INTRODUCTION

In the presentation of *projective techniques* four steps will be taken:

1 The first step focuses on the definition, general characteristics, classification and dominant theoretical perspectives on projective techniques.
2 Given the high number and diversity of these techniques it was decided to elect the one most known and used among them, the Rorschach Inkblot Method, for a larger appreciation of its development. Particular emphasis will also be given here to the Exner Comprehensive System that was gradually developed as from the late 1960s.
3 The third step considers the impact of and reactions to the Comprehensive System in the scope of projective techniques and psychological measurement.
4 The final step includes some comments about the future of projective techniques.

DEFINITION AND GENERAL CHARACTERISTICS

Projective techniques designate a set of instruments whose main objective is to describe and characterize personality.

The adjective *projective* is a derivative of 'projection', a concept introduced by Freud in the vocabulary of psychology to describe the design of a defence mechanism leading the subject to transfer to another person, or thing, his urges, feelings, etc., that he cannot accept as belonging to him. However, this concept is not commonly used in the field of projective techniques. Rather, another concept with a less restrictive and specific meaning is used. This means that, in responding to the stimulus-situation, the subject reveals or externalizes aspects of his own personal life, such as motives, interests, feelings, emotions, conflicts and the like.

To a large extent, the characteristics of the stimuli of the projectives are responsible for this externalization and have an important effect on the nature and content of the subject's responses. Two such characteristics are the structure and ambiguity of stimuli. The structure refers to the degree of organization of the stimulus: incompleteness, nearly an organized whole or fully divided, close to or far from being a real representation, etc. The ambiguity concerns the number and variability of responses each stimulus elicits.

Due to the different nature of the material and response modalities that these techniques involve, they have been classified in many ways. Table 1 presents Fernández-Ballesteros' classification, and includes the most representative examples of each class. For many years, they have been controversial in the sphere of assessment and measurement in Psychology.

Multiple factors of intrinsic and extrinsic nature have contributed to this state of affairs. Where the extrinsic factors are concerned, they are integrated

Table 1. Projective techniques: classification and examples (Fernández-Ballesteros, 1980)

Structural	Thematic	Expressive	Associative	Constructive
Rorschach Inkblots	Thematic Apperception Test	Drawing of the human figure	Free Association Test	Town Test
Holtzman Inkblot Technique	Children Apperception Test (CAT-A; CAT-H)	House–Tree–Person (H-T-P) Test	The Incomplete Sentences Test	Test du Village Imaginaire

into the vast group of measuring instruments, globally known as psychological tests. They have mainly been applied in pathological or clinical psychology. Here, the idiographic perspective has either been prevalent or has tended to be exclusive in contrast with the nomothetic nature of the tests. As far as the intrinsic factors go, the lack of structure and the ambiguity of stimuli are only some of the most important features which have previously been pointed out.

The only things in common between the projective techniques and the tests are the standardized character of the stimulus and the method of administration. Since there are no right or wrong answers, the record is generally not subject to correction or classification in the clinical context of its use, but mainly to analysis and interpretation.

The first important study on this subject was by Frank, in 1939: as article 'Projective Methods for the Study of Personality' (Frank, 1939). It was decisive in defining the status of the projective techniques and their future course as a target for support and dedication or rejection and hostility. In the projective methods, Frank saw suitable instruments for studying the individual as such, since by answering, he organized the unstructured field (the stimulus) according to his skills and projected personal life experiences. Owing to kind of observation and assessment, on the one hand, the aim was to exclude the presence of the examiner, in designing the stimulus intentionality, and, on the other, it was supposed to suppress the comparative judgemental element between individuals, implicit upon consulting normative tables.

In effect neither was the subject excluded as he continued to be an important part of the situation, nor were the norms dispensable, because without them it would not have been possible to identify the degree of individuality conveyed. Little by little, it was acknowledged that as instruments of assessment, the projective techniques were not able to side step the requirements of reliability and validity inherent in them.

Normative studies were not the rule. Rosenzweig and Fleming (1949) and Eron (1950) respectively developed apperceptive and thematic norms for the TAT. Murstein enhanced the importance of the stimulus (1963), made clear the difference of structure and ambiguity of the stimulus. Bearing in mind the need to meet the measuring requirements of psychological tests, Holtzman conceived a tool composed of 45 inkblot cards, called the Holtzman Inkblot Technique (HIT) (1961). By asking his subject to give only one answer per card, he was able to control the number of responses, considered to be a real pitfall in the Rorschach.

With respect to reliability and validity, it was seen that studies frequently suffered from difficulties and methodological inaccuracies. In Europe, the scenario was not encouraging for several reasons to do with historical, ideological and social factors. The concern for reliability and validity of the projective techniques scarcely mattered. It can be said that normative studies involving projective techniques were rare and of limited scope in Europe.

A factor that largely influenced the critical profile attributed to the projective techniques was its association with the psychoanalytical theory of personality, so much so that a co-dependent relationship seemed to exist between them. There is no doubt about the fact that psychoanalytic theory has been the basis for a great number of projective techniques, or that it has been the dominant perspective of interpretation. To a great extent, this position corresponded to the development of the psychoanalytical theory of the time.

THE RORSCHACH AND EXNER CONTRIBUTION

Herman Rorschach, born in 1884, was a Swiss psychiatrist who administered a set of inkblots made up by himself, to his patients. He would

ask them to say what they saw in the inkblots or what might they represent. This practice later came to constitute a 'psychological experiment' whose nature, aims, and results were the subject matter of a monograph entitled *Psychodiagnostics: A Diagnostic Test Based on Perception* (1921/1942). H. Rorschach's premature death in 1922 prevented him from further developing his work and its theoretical basis, which he regarded in the short *Introduction* to his book (1921) as still 'embryonic'. The latter has become the object of the study and research of many scientists throughout the years.

Rorschach presented his test as an essentially perceptive task. Responses to the instructions – W*hat might this be?* – were codified according to three main dimensions: location (where the subject saw the designed object), determinants (what led up to the view of this object) and content (what the object is). His work, study and observation of patients allowed him to find or identify several conceptual meanings for his new variables. On this basis, he elaborated guidelines for interpreting the patient's records which allowed him to draw up a statement of personality characteristics.

The core of Rorschach's test has essentially been passed down from one author to another, without undergoing any radical changes. As the fruit of clinical practice and/or research, here and there several new variables have been introduced by different authors.

Exner's contribution. Several factors have contributed to the fact that the Rorschach was somewhat discredited throughout the 1960s. In confronting this situation, Exner took it upon himself to provide the Rorschach with the kind of characteristics a test should have: reliability and validity. Method was his main weapon.

From the revision, analysis, and comparison of the five Rorschach systems effective in the USA – the Beck, Hertz, Klopfer, Piotrowsky and the Rapaport-Schafer – Exner retained what seemed to him to be the most consistent parts in order to build what he called the Comprehensive System (CS) (Exner, 1974). His guiding criterion was objectivity, present throughout each of the steps to standardize the test's whole administration procedure in order to make sure that the record constituted a valid sample of the subject's behaviour, a mediator of his personality. Defining and establishing precise criteria of coding which attempted to preserve the answer as it was given, without submitting it to subjective decisions, allowed for high levels of interscorer reliability.

The interpretative process was fully delineated; it was adjusted to different records according to specific characteristics, and was organized so as the records could be analysed and considered as a whole and not only partially.

Reliability studies. In projective techniques coding or scoring reliability is the *sine qua non* condition of test reliability.

Reliability studies in projective techniques have their own limitations due to their very nature. With the exception of studies based on Exner's CS, studies concerning most of the projective instruments are rare. The kind of study adopted resulted from reflection upon and knowledge about the nature of the materials, the answers and the variables. Using this approach in a reliability study brings to light the following three considerations: (a) when examining reliability in the Rorschach, what is at stake are the variables, mainly the determinants, and not the contents; (b) even though personality may change, it is generally acceptable that it will not change considerably over short or long periods of time, in accordance with the different ageing periods; (c) with reference to memory effect, it is important to realize the fact that the subject's response is only one among several he might have given.

Two implications of considerable interest deriving from temporal consistency studies should be mentioned. The first was the fact that several variables presented various low levels of reliability, on par with others that reached medium or high levels. It was thus possible to identify some variables which resembled state variables in terms of temporal consistency; at times, some variables had the appearance of state variables while at others, they seemed to be trait variables; yet other variables attested to the enduring characteristics of personality. The second implication referred to short records of less than 14 answers and were considered as lacking reliability. Consequently, as a rule, their interpretation was not valid.

Validity studies. As with reliability, it is also clear that not all modalities of test validating are suitable for projective techniques, namely the Rorschach. Mary Ainsworth, in a chapter entitled *Problems of Validation* (1954), believes that the

study of validity of the Rorschach does not have the same characteristics as personality tests. In regarding the Rorschach as an observation method and not as a test, Ainsworth believes that the hypothetical constructs connected to the several variables should be the object of validation (Ainsworth, 1954: 405–406).

There were numerous validation studies undertaken as the CS was being developed. They are referred to in Exner's three volumes (1991, 1993, 1995) although they were obviously unfinished at the time of writing. On the other hand, the last few decades have seen the emergence of a considerable number of validity studies not only connected to the Rorschach but also to different scales and indices deriving from it and designed to assess specific aspects.

A concept which became very important in the CS, dating from the publication of Volume 1 in 1993, had to do with *personality styles*. They were defined as '... features that give rise to psychological and behavioural response tendencies, sometimes only in specific situations, but more often as a general preference for a particular approach to problem solving or decision making' (Exner, 1993: 404). This new concept lay behind the decision to publish different normative tables according to different styles. In the same volume, norms were published for three coping styles: the introversive, the extratensive and the ambitent. In the most recent edition of *A Rorschach Workbook for the Comprehensive System* (Exner, 2001), a fourth table was introduced that referred to the high lambda style. This style is characterized by the fact that a half or more than a half of the responses given in subjects' records have a *Pure F* determinant.

IMPACT OF AND REACTIONS TO THE COMPREHENSIVE SYSTEM

After more than thirty years' work, study and research, the Rorschach seems to have gained its rightful scientific status. Some events in the field of projective techniques, which are seemingly linked to the success achieved by the CS, are underlined as follows:

- the appearance of normative studies on the Rorschach and other projective techniques here and there all over the world;
- the publication of a valuable work on research methodology;
- the integration of an empirical and psychoanalytic approach;
- extending the CS so as to integrate, within the interpretation process, some aspects like card pull, thematic content, test behaviours and sequence analysis that were formerly considered in well-known systems;
- attending to teaching personality assessment, namely projectives.

Some points should be stressed concerning the field of reactions. One of them has to do with the results of recent new studies on normative data coming from the USA. Reacting against the idea that the CS norms were adapted to both American and non-American citizens, the results obtained distinctly showed that the same could not be said at least with regard to Belgium, Chile, Denmark, Finland, Portugal, Spain and Venezuela.

Another point that should be emphasized is Weiner's conceptual approach to the Rorschach. He prefers seeing it not as a test but rather as a method – the Rorschach Inkblot Method (RIM): 'a method of generating data' (1995: 29). As current kinds of behaviour, these data can be interpreted from any theoretical perspective on personality. These two main ideas – there is no theoretical ownership of the Rorschach and the Rorschach is a method, not a test – contain two important aspects: firstly, the Rorschach is now a reliable and valid method, one which is confirmed by the CS; secondly, its data may be analysed and interpreted according to any theoretical approach. This perspective preserves both the empirical and objective qualities of the instrument and the idiographic dimension required by personality assessment and clinical practice.

Several articles presenting reviews of research related with projective techniques, namely the CS, have been published in the last few years, their comments and conclusions not always heading in the same direction.

In spite of intermittent publications of critical reviews throughout the years, projective techniques have endured and have actually benefited from the criticism. Once in a while, an author asks why projective techniques continue being used after so much evidence has been produced

condemning their lack of quality as assessment tools. One of the main reasons for their persistence and survival hinges on the fact that common personality tests do not supply the clinician with the holistic nature of their products and access to the idiographic. The proponents of projective techniques are confident that they are working in a suitable way and they are generally convinced that they will improve. It is a question of time, intelligence, study and research.

All the work and research using the Rorschach and carried out by Exner and his colleagues reveal very important information that holds true for every other projective technique. Given the nature of their stimuli, we do not exactly know what they measure. To learn this and understand why they measure what they do, we always have to question both the stimulus and the theory, or go from one to another and come back again. Theory gives meaning to the response but a response is determined by the stimulus that elicits it.

FUTURE PERSPECTIVES

In the light of Weiner's formulation, we can say that all projective techniques are methods that generate structural, thematic and behavioural data (1997: 6). Until now, psychologists have centred their attention on analysing and interpreting data according to their theories. They have been much less concerned about the source of the data and their nomothetic dimension. Because nomothetic and idiographic approaches condition each other up to a point, on the basis of past research we can easily predict that something which advances in one direction may correct the way or reveal new fields in the other. There is no reason to assume that an exclusive relationship exists between these two approaches.

From this point of view, an extensive working agenda now faces projectivists. As a matter of fact, empirical studies on projective techniques are clearly insufficient and frequently of an elementary level. If the study of stimulus properties is necessary, then experimental or quasi-experimental designs must be on the horizon of their research. This is also the way to validate theories.

An important aspect that should be the focus of attention for the future study and research of projective techniques lies in the relationship frequently established between certain variables and concepts. It frequently happens that there is no clear explanation for such a relationship. On the other hand, projective techniques are very often used with diagnostic aims. Although this is feasible, we should previously know which of the personality characteristics give rise to or are the effect of the diagnosed disorder. In following this up, we need to learn whether this characteristic may be identified by using a projective technique. Only then may a diagnosis be made (Weiner, 1997: 11). A large source of work is to be found here.

In a conference in Lisbon, in 2000, Exner referred to a number of positive human qualities like affection, consideration, optimism and so on, whose expression in projectives is unknown, thus indicating that a greater number of variables need to be studied. From the perspective of new fields of assessment, where the contribution of projective techniques may be required – health psychology, forensic psychology, treatment planning and evaluation, cross-cultural and multicultural psychology – it is easy to perceive that widening the scope is both pertinent and important.

CONCLUSIONS

Projective techniques, as methods of assessing and describing personality, are alive and well, and do not seem to have been relegated to second place in favour of the so-called objective assessment methods. They continue to be preferred and used by a large number of psychologists in both the former and the new fields of psychological assessment. Among the different theoretical approaches on projective data, there are still two predominant currents: the psychoanalytical perspective according to its current theory of object relation which leads to an intuitive interpretation that is largely dependent on the interpreter; the perspective that aims to endow these instruments with psychometric qualities of reliability and validity, whereby the data may be interpreted in the light of any personality theory including psychoanalysis.

CS has had the merit of giving the Rorschach a suitable methodology of use, study and research that, when adjusted, may be applied to other projective devices whenever it is needed. It has also been shown that teaching and training in this area is urgent and of primary importance.

Nevertheless, from what has been said here, we are still able to confirm the fact that seeing the projective techniques in action is almost unknown. However, if this state of affairs is true, then the pathways leading to their study and research promise to be wide and fruitful.

PROSOCIAL BEHAVIOUR

INTRODUCTION

Prosocial behaviour refers to voluntary behaviour aimed to benefit other persons, regardless of the benefactor's motives. It includes a variety of behaviours like sharing, donating, caring, comforting and helping and is often associated with altruism because both concepts involve the pursuit of another's good and may imply common components such as empathy and sympathy (Batson, 1998; Eisenberg & Fabes, 1998; Schroeder, Penner, Dovidio & Piliavin, 1995). In this entry, a number of issues related to the determinants and functions of prosocial behaviour are described, drawing from main directions of research and from recent findings.

DETERMINANTS AND FUNCTIONS OF PROSOCIAL BEHAVIOUR

Although the importance of being able to benefit others is quite obvious for the quality of social interactions between individuals and among

groups, the determinants of prosocial behaviour – that is, the mechanism through which it operates and the functions that are ultimately served – remain problematic. On the one hand, it is a matter of debate the extent to which most prosocial behaviour reflects intrinsic altruistic inclinations or motives, or is ultimately instrumental to the satisfaction of egoistic needs like social approval and self-acceptance. Indeed, one may be led to benefit others and even to sacrifice one's own interests and safety for the good of others because of other self-oriented reasons, including feeling good, impressing others, serving an ideal or fulfilling a prophecy. Thus, one may argue that the helper's intentions and expected rewards qualify the nature of prosocial behaviour as either altruistic or egoistic, or a mixture.

On the other hand, the extent to which prosocial behaviour is adaptive for individuals versus society is not clear. Early philosophers addressed these issues as part of their speculation on human nature, reason, and morality. Some, like Thomas Hobbes, conceptualized egoism and self-love as essential traits of human nature and viewed prosocial conduct as an instrumental act that is acquired only to preserve society. Others, like Jean Jacques Rousseau, conceived benevolence and sensitivity towards others as innate propensities that may be corrupted by society. Early personality psychologists echoed these philosophical assumptions when they addressed prosocial and related behaviours, mostly in the context of their reflections on personality development and adjustment. Whereas Sigmund Freud focused on the defensive aspects of prosocial motives, Abraham Maslow advocated the capacity to love, to care, and to transcend contingent self-interest.

Over recent decades, several arguments have been proposed in support of the biological value of altruistic prosocial behaviour on the assumption that evolutionary selection operates mostly through groups other than through individuals. Individual sacrifices are often required to preserve the pool of genes that maximizes the capacity of the species to adapt to the changing environments (Wilson, 1975, 1978). Furthermore, because the potential costs of giving aid to others are often compensated by receiving help from others, reciprocal altruism has gained survival value in predisposing individuals to behave altruistically and to expect that others will perform altruistically toward them (Trivers, 1971). Both heritability and stability coefficients offer some support for the hypothesis that the tendency to behave prosocially is part of our genetic endowment. However, most evolutionary hypotheses are difficult to prove, and the processes and mechanisms through which heredity shapes altruistic motives and behaviour remain highly controversial.

In contrast, there is an abundance of evidence that culture, socialization practices and experience play critical roles in setting the conditions and in predisposing individuals to prosocial behaviour, as well as in qualifying its different forms. Indeed, the ways that another's well being is given meaning and is pursued reflect systems of values, norms, and habits that vary significantly across cultures and social contexts.

ASSESSMENT ON SELECTED RESEARCH AREAS

Because systematic research on prosocial behaviour has been conducted mostly in western culture, unavoidably it reflects the basic assumptions of that culture about the self in relation to others and society, namely the role assigned to personal agency and to individual responsibility in moral reasoning and action. Thus one should generalize with caution findings from one context to another. Nor can one generalize from one domain of research to another without due caution.

Social Psychology

Social psychologists have focused on the role of situations in fostering or discouraging helping behaviour, as well as on the role of social norms related to reciprocity and responsibility (Taylor, Peplau & Sears, 2000). Previous exposure to helping models, emergency situations in which persons are suddenly and unexpectedly under threat, similarity with persons in need, explicit requests for help, and the absence of others who could help the victim are all contingencies that have been found to raise the probability that one will take supportive action. Being in a good mood also may foster helping behaviour, and feelings of guilt may induce one to engage in prosocial behaviour when it may relieve the guilt and restore self-approval. Social norms of reciprocity,

responsibility, and justice largely prescribe when, how, and whom one will help.

Most of the findings of social psychologists derive from laboratory studies and quasi experiments, which have limited generality across persons and situations and problematic representativeness of real life helping contingencies. Assessment methods include observation of behaviour in situational tasks and self-reports.

Developmental Psychology

Developmental psychologists have focused first on the influences that learning, cognitive development, and moral development exert on the development of prosocial behaviour and, more recently, on the influences that emotions and interpersonal relations exert on prosocial behaviour in order to develop stable representations of oneself, positive attitudes towards others, and motives and habits to benefit others (Eisenberg & Fabes, 1998; Mussen & Eisenberg, 2001). Models, preaching, instructions, and reinforcements are no less important than the experience of being nurtured, cared for, and valued, although the evidence for a direct link between parental warmth and a child's prosocial tendencies are not as strong as object relations and attachment theorists would suggest.

Likely, the degree of association between parental nurturance and prosocial responding by a child varies across development, across behaviours, and across situations, and is moderated by temperamental and personality characteristics of children and parents, as well as by other contingencies, such as the presence of siblings and socialization practices related to management of emotions. Empathy, as reflected either in the capacity to take the perspective of others or in the capacity to sympathize with another's feelings, is crucial in setting the individual conditions that promote prosocial behaviour toward others. Direct experiences of having been helped by others as well as of helping others are both critical to being able to appreciate the consequences of prosocial behaviour fully.

Although family relations largely paves the way to all the above factors, the influence of friends and peers is more and more important as children move out of the family to test their perceptions of themselves and others and their strategies to deal with the world. Peer interactions provide further and unique occasions beyond the home to experience prosocial behaviour as both agent and target and, thus, to capture the sense of concepts like fairness, justice, and reciprocity.

Yet another direction has addressed the correlates and functions of prosocial behaviour.

Even though girls are often more prosocial than boys, the inclination to behave prosocially is moderately stable from infancy through to adolescence in both males and females (Caprara, Barbaranelli & Pastorelli, 2001). Prosocial behaviour has proven to be moderately and positively correlated with a variety of favourable individual characteristics, including social competence and well adjustment in children and adolescents (see Eisenberg & Fabes, 1998). Further findings have corroborated the protective role of prosocial behaviour in buffering one from depression and transgressive behaviours and in sustaining scholastic achievement from infancy to early adolescence (Bandura, Barbaranelli, Caprara & Pastorelli, 1996; Bandura, Caprara, Barbaranelli, Pastorelli & Regalia, 2001; Bandura, Pastorelli, Barbaranelli & Caprara, 1999; Caprara, Barbaranelli, Pastorelli, Bandura & Zimbardo, 2000).

Findings of developmental psychologists derive from a variety of sources, including laboratory studies and systematic and prolonged observations within the family and in various natural settings. Assessment methods include ratings of others, peer nominations, and self-reports. Early and subsequent versions of Caprara and Pastorelli's mono-factorial scale (1993), including items for sharing/donating, caring/comforting, and helping, have proven to be valid across several languages for both children and adults.

FUTURE PERSPECTIVES

As research addresses the psychological processes and mechanisms that underlie prosocial behaviour and begins to explain its stability across time and situations, the developmental psychologist's agenda converges with that of the personality psychologist to focus on the cognitive-motivational systems and structures that constitute the core of personality as a whole, coherent agentic system. One joint current direction concerns the dynamics of prosocial behaviour, namely the processes and mechanisms that underlie the intentions of an actor

and the act of benefiting another, and the transactions of influence between the two. Because prosocial behaviour implies first a decision to help, which turns into an intention and then the act of pursuing this intention, the study of the dynamics of prosocial behaviour leads one to focus on the cognitive-motivational structures that guide the decision and grant its achievement, including self-beliefs, outcome expectations, values, and personal standards.

Because most findings derive from children and adolescents, one can only guess the extent to which the positive function that prosocial behaviour has proven to exert in childhood and adolescence will also extend over the course of life, namely through seasons of life in which the greater need to be helped by others can be well compensated by individuals' capacity to help others.

CONCLUSIONS

As recently stated by Eisenberg and Fabes, 'the study of prosocial development is still in its adolescence; much work has been conducted since 1970, but both relevant theory and conceptual integration of existing empirical findings are in need of further development' (1998: 702). Other areas of study, such as aggression and hostility, have received more attention than prosociality and altruism, likely because of their interference with even basic social functioning. This research has led to a focus on prevention and repression of undesirable social behaviours. However, it may be that a focus on the development of prosocial behaviour will turn out to be the most effective strategy for preventing aggressive behaviour.

Although most research has been conducted on children and adolescents and continues to target early development, the advantages of prosocial behaviour are likely no less important for the achievement of excellence and in the pursuit of happiness over the course of life.

In this regard, the study of prosocial behaviour is a critical step towards its promotion.

PSYCHOEDUCATIONAL TEST BATTERIES

INTRODUCTION

Psychoeducational test batteries are designed to provide a comprehensive assessment of an individual's strengths and weaknesses across a wide range of skills and abilities. Unlike standardized diagnostic testing which is used primarily to assess mastery of specific goals and objectives or areas of deficit (e.g. a commercially available norm-referenced test of mathematics), comprehensive test batteries are more general in focus, sampling from a broad array of skills within a particular domain. To date, the domains most typically represented are those of (a) cognitive or intellectual abilities, and (b) broad-based academic achievement. Each of these domains is then represented by a variety of subtests that are designed to assess the specific features of their respective domains. That is, the cognitive or intellectual portion of the psychoeducational test battery would contain a number and variety of subtests purported to assess specific features of intellectual development (e.g. short- and long-term memory, fluid and crystallized reasoning), and the academic achievement portion of the battery would be organized tasks associated with the process of schooling (e.g. reading, spelling, mathematics, written expression).

The use of psychoeducational test batteries offer two major advantages in clinical use (Salvia & Ysseldyke, 1995). First, from a technical adequacy standpoint the use of the same normative sample provides derived scores across domains that are logically linked. Simply, observed scores across domains (i.e. cognitive and achievement) are directly comparable since they were derived from the same normative sample. This helps alleviate the problems brought about by the indiscriminate practice of comparing observed scores obtained from tests with different normative samples. For example, if a student obtains a score of 100 (mean = 100, standard deviation = 15) on a test of cognitive or intellectual development and a score of 92 on a test of academic achievement it is difficult, if possible, to determine if such a difference is indeed true or a result of differences in the norms of the two tests brought about as a function of the two different normative samples.

Second, psychoeducational test batteries provide psychologists and clinicians a convenient method for assessing a broad array of skills across multiple domains with one test. In doing so, the assessor avoids redundancies in assessment that may come about as a result of combining tests that are not co-developed and share similar assessment features. Because psychoeducational test batteries are developed from a uniform theoretical perspective, they are less likely to assess the same underlying specific abilities across subtests and domains. Doing so reduces repetitious assessment and facilitates interpretation.

SPECIFIC PSYCHOEDUCATIONAL TEST BATTERIES: WECHSLER INTELLIGENCE SCALE FOR CHILDREN – THIRD EDITION AND THE WECHSLER INDIVIDUAL ACHIEVEMENT TEST

The *Wechsler Intelligence Scale for Children – Third Edition* (WISC-III; Wechsler, 1991) is the most recent version of the Wechsler scales for children ages 6 through to 16 years old. The WISC-III is made up of 13 subtests that comprise a Verbal Scale IQ, a Performance Scale IQ, and a Full Scale IQ. By design, the Verbal Scale attempts to measure verbal comprehension and includes the application of verbal skills and information to the solution of new problems, the ability to process verbal information, and the ability to think with words. Comparatively, the Performance Scale is designed to measure perceptual organization and involves visual processing, planning and organizational ability, and non-verbal learning and memory.

Although marketed a year later, *the Wechsler Individual Achievement Test* (WIAT; The Psychological Corporation, 1992) is the companion achievement test to the WISC-III. Like the WISC-III, it is individually administered and covers the areas of reading, mathematics,

language skills, and writing. It is designed for use with children and young adults between the ages of 5 and 19 years. Following is a brief description of the subtests that comprise each instrument.

WISC-III Verbal Scale

- *Information*. Requires the child to answer factual questions presented by the examiner.
- *Similarities*. Requires the child to answer questions about how objects or concepts are alike.
- *Arithmetic*. Requires the child to answer simple to complex arithmetic problems involving concepts and numerical reasoning.
- *Vocabulary*. Requires the child to orally define words presented by the examiner.
- *Comprehension*. Requires the child to respond orally to questions posed by the examiner involving interpersonal relations and social mores.
- *Digit Span*. Requires the child to repeat a series of numbers that are dictated by the examiner.

WISC-III Performance Scale

- *Picture Completion*. Requires the child to identify an important missing element from a picture.
- *Coding*. Requires the child to copy symbols according to a specified pattern as quickly as possible.
- *Picture Arrangement*. Requires the child to place a series of pictures depicting a scene in a logical order.
- *Block Design*. Requires the child to reproduce designs using three-dimensional blocks.
- *Object Assembly*. Requires the child to put puzzles of common objects together.
- *Symbol Search*. A supplementary subtest that requires the child to look at a symbol and then decide if it is present in an array of symbols.
- *Mazes*. A supplementary subtest that requires the child to solve paper-and-pencil mazes of increasing complexity.

WIAT

- *Basic Reading*. Requires the child to identify letters and read words in isolation.
- *Reading Comprehension*. Requires the child to read passages of increasing length and difficulty and answer questions.
- *Mathematics Reasoning*. Requires the child to respond to a broad range of mathematics skills including counting, number recognition, and word problems.
- *Numerical Operations*. Requires the child to solve computation problems.
- *Listening Comprehension*. Requires the child to demonstrate knowledge of vocabulary, following directions, and general listening comprehension.
- *Oral Expression*. Requires the child to demonstrate knowledge of expressive vocabulary, given directions, and providing oral accounts of actions.
- *Spelling*. Requires the child to write individual letters and words that are dictated.
- *Written Expression*. Requires the child to express ideas in a written fashion.

Technical Data

Standardization

The WISC-III was standardized on 2,200 children stratified by age, race/ethnicity, geographic region, and parental education. One-hundred boys and girls constitute each of 11 age groups ranging from 6 through to 16 years. The WIAT standardization sample was similarly stratified and consisted of 4,252 students in 13 age groups, ranging in age from 5 to 19. To link the WIAT to the WISC-III, a subset of 1,284 students were administered both the WISC-III and the WIAT during the standardization process.

Reliability

The WISC-III has very good reliability. Average internal consistency reliability coefficients are 0.96 for the Full Scale IQ, 0.95 for the Verbal Scale IQ, and 0.91 for the Performance Scale IQ. Similarly, median stability coefficients are 0.94, 0.94, and 0.87 for the Full, Verbal, and Performance Scales, respectively. Likewise, the WIAT exhibits median internal reliability coefficients of 0.88 across the eight subtests. Test–retest coefficients over a 17-day period range from 0.61 to 0.96 ($Mdn\ r_{tt} = 0.85$) for the subtests and from 0.65 to 0.97 ($Mdn\ r_{tt} = 0.93$) for composite scores.

Validity

Correlations between the WISC-III and other cognitive ability tests are high. Concurrent validity studies report that the WISC-III Full Scale IQ correlates 0.89 with the previous version of the test, and 0.86 and 0.85 with the preschool and adult versions of the test, respectively. Predictive validity coefficients with school achievement are in the range of 0.50 to 0.65 with the Verbal Scale more highly correlated with academic achievement than the Performance Scale. Correlations between WIAT scores and Full Scale IQs range from 0.30 to 0.84 (*Mdn* $r = 0.58$). In addition, criterion-related validity is adequate as noted by high correlations ($7 = 0.68$ to 0.88; *Mdn* $r = 0.81$) between the WIAT and the *Basic Achievement Skills Individual Screener*, *Kaufman Test of Educational Achievement*, and the *Wide Range Achievement Test – Revised*.

KAUFMAN ASSESSMENT BATTERY FOR CHILDREN

The *Kaufman Assessment Battery for Children* (K-ABC; Kaufman & Kaufman, 1983a, b) is an individually administered norm-referenced battery intended to provide a comprehensive assessment of cognitive and intellectual abilities and academic achievement for children ages 2-6 to 12-5. Sixteen subtests are combined into three regularly administered scales and one supplementary scale. Cognitive intellectual abilities are assessed across ten subtests yielding two factor or scale scores: (a) Simultaneous Processing Scale, and (b) Simultaneous Processing Scale; and one combined or total score referred to as a Mental Processing Composite. According to the authors, simultaneous processing refers to the ability to integrate input all at once to solve a problem correctly; while sequential processing emphasizes problem solving where correct responding rests on the ability to arrange stimuli in a sequential or serial order. In addition to the Mental Processing subtests, six Achievement subtests are administered intended to assess factual knowledge and skills usually acquired through interactions with the environment or the process of schooling. Finally, a Nonverbal Scale is available which combines subtests across the simultaneous and sequential scales and is intended to be an estimate of intellectual functioning for children who are deaf, hearing-impaired, speech or language-impaired, or non-English speaking. Following is a brief description of the subtests that make up each scale.

Sequential Processing Scale

- *Hand Movements*. Requires the child to imitate a series of hand movements in the same sequence as the examiner performed them.
- *Number Recall*. Requires the child to repeat a series of numbers presented aurally by the examiner.
- *Word Order*. Task which requires the child to touch a series of pictures in the same sequence as they were named by the examiner.

Simultaneous Processing Scale

- *Magic Window*. Requires the child to identify a picture that is progressively presented by the examiner through a narrow slit or a window.
- *Face Recognition*. Requires the child to select from a group photograph faces of people who were shown briefly in a preceding photograph.
- *Gestalt Closure*. Requires the child to name an object or scene that is only partially pictured in an inkblot type drawing.
- *Triangles*. Requires the child to assemble triangles to match an abstract design modelled on a card.
- *Matrix Analogies*. Requires the child to select a picture or design that completes a visual analogy.
- *Spatial Memory*. Requires the child to recall the placement of pictures on a page that was exposed for a 5-second interval.
- *Photo Series*. Requires the child to place photographs that illustrate an event in chronological order.

Achievement Scale

- *Expressive Vocabulary*. Requires the child to name objects that are pictured in photographs.
- *Faces and Places*. Requires the child to identify well-known people, fictional

characters, or places pictured in a photograph or illustration.
- *Arithmetic*. Requires the child to answer questions that assess knowledge of maths concepts or the manipulation of numbers.
- *Riddles*. Requires the child to name an object or concept that is described by a list of three of its characteristics.
- *Reading/Decoding*. Requires the child to name letters and read words in isolation.
- *Reading/Understanding*. Requires the child to act out commands that are given in words or sentences.

Technical Data

Standardization

The K-ABC was standardized on 2,000 children ages 2-6 to 12-5 with 100 students sampled at each half-year age range. The sample was stratified by age, gender, geographic region, race/ethnicity group, parental educational attainment, community size, student educational placement, and disability category according to the 1980 US Census and the National Center for Education Statistics. In addition, sociocultural norms are provided for comparison of a child to others of similar racial and ethnic background and socioeconomic status on the Mental Processing Scale and the Achievement subtests.

Reliability

Internal consistency reliabilities for the Mental Processing Composite and the Achievement Scales are excellent for both preschool ($r_{xx} = 0.91$ and 0.93, respectively) and school-age children ($r_{xx} = 0.94$ and 0.97). Stability of the K-ABC measured over a retest interval of 2 to 4 weeks is adequate, with a median coefficient of 0.88 for the Mental Processing Composite and 0.95 for the Achievement Scale.

Validity

Evidence of construct validity is presented in the form of increases in subtest raw scores as a function of age. Criterion-related validity has also been examined correlating the K-ABC with other similar measures. Correlation between the Mental Processing Composite and the Full Scale IQ of the WISC-R is reported to be 0.70. Predictive validity has been examined by correlating the K-ABC with other measures of achievement. Overall, the K-ABC has demonstrated adequate predictive validity for both group ($r_{xy} = 0.65$) and individually administered ($r_{xy} = 0.79$) tests of achievement.

FUTURE PERSPECTIVES AND CONCLUSIONS

As can be seen, the main advantage of psychoeducational test batteries is that one standardization sample is used for all domains. Therefore, differences between domains within a particular test battery do not result from differences in standardization samples, and the clinician can be confident in knowing that the differences were not a result of uncontrolled error brought about by different samples. In addition, their construction allows clinicians to sample from a wide variety of constructs and behaviours with a minimal amount of assessment time. Psychometrically, most commercially available batteries demonstrate adequate levels of reliability and validity and are well researched with respect to their technical adequacy.

Be that as it may, psychoeducational test batteries are not without their shortcomings. First, from a content validity perspective, the extent to which the batteries tap into the two main constructs of interest (i.e. cognitive/intellectual abilities, academic achievement) is speculative. On the cognitive ability side, each of the measures are developed from differing theoretical perspectives, each of which purports to measure cognitive/intellectual growth. Debates regarding intellectual development are largely unsettled and assessing the accuracy of various measures proves difficult. On the achievement side as well, the extent to which the tests overlap with that which is found in common school curricula is low. Simply, the extent to which the tests sample from the larger domain of academic achievement is dubious at best. These issues are compounded by a response format that does not mirror the behaviour as it is performed in the natural environment, as well as an overall lack of treatment utility. Clearly, such tests have limited use in planning instruction.

DEVELOPMENT (GENERAL), APPLIED FIELDS: EDUCATION

PSYCHONEUROIMMUNOLOGY

INTRODUCTION

Psychoneuroimmunology (PNI) is an interdisciplinary field which studies the relationships between neural and endocrine function, and immune processes. More specifically, PNI attempts to elucidate the relations among behavioural and psychosocial factors, nervous, endocrine and immune systems, and health (Ader & Cohen, 1993; Bachen, Cohen & Marsland, 1997).

PNI is a relatively young discipline, though speculations about relationships between mind and body have recurrently been part of Western thought over the centuries. However, it was in the beginning of the last century that several precedents to the scientific study of the interactions between behaviour and immune function began to appear. Particularly, two Soviet researchers, Metalnikov and Chorine, in the 1920s, produced a Pavlovian conditioning of a variety of non-specific defence responses and antibody production in rabbits in response to heat and tactile stimulation as conditioned stimulus (see Ader, 1981 for an historical review of conditioned immunobiological responses). Furthermore, in the 1960s Solomon and Moos (1964) published their paper 'Emotions, Immunity, and Disease' which synthesizes the relations of stress, emotions, immunological dysfunction (especially autoimmunity), and physical and mental disease.

Nevertheless, it was in the late 1970s and the beginning of the 1980s, after Ader and Cohen's (1975) seminal work on conditioned modulation of immunity (a great example of scientific serendipity), when PNI was founded.

PSYCHOLOGICAL STRESS AND IMMUNITY

One of the most fruitful as well as promising issues in PNI research has been the relationships between stress and immunity. The possible link between neural, endocrine and immune systems deserves particular interest in view of its potential relevance for health maintenance and to its aetiopathogenetic implication in several diseases (Bayés & Borrás, 1999).

A review of the studies which have been carried out on this topic shows that they can be divided into several categories according to different criteria. On the one hand, regarding the population, animal versus human studies. Among human studies, healthy versus non-healthy human subject studies.

On the other hand, regarding the type of stress subjects have to cope with, those which explore the effect of chronic stress such as major life events (divorce, bereavement) versus acute stress, such as short-term laboratory stressors (loud noise, unsolvable puzzles) or academic examinations.

Focusing on studies in human beings, the PNI assessment depends on the role of the variables used and the character of the studies. As an interdisciplinary field, as PNI is, it uses assessment instruments and procedures from other disciplines rather than develops its own methods. Generally speaking, it might be distinguished between the procedures for directly assessing the immune function and those for measuring the health status and disease. The first of them are especially useful for healthy population research even though they give some doubts about the clinical relevance of findings. The second offer an approach to disease research though those parameters might be less reliable and present several methodological problems.

THE ASSESSMENT OF IMMUNE FUNCTION

The assessment of immune function is made by immunological assays. There are two different types of immunological assays: enumerative and functional assays.

Enumerative Assays

Enumerative assays provide information about percentages or number of cells. Usually, they quantify lymphocyte subsets using monoclonal antibodies with fluorescent dye which are directed at specific surface antigens. After lymphocyte incubation, it is able to count the number of cells of the specific subset. Parameters such as T-cell account, helper/inducer T-cells ratio, B-cells number, NK number, serum IgE levels and salivary IgA (sIgA) are commonly used in PNI studies.

However, some of these parameters have been criticized as unreliable measures of the 'immunocompetence' for PNI studies (Schulz & Schulz, 1992). For instance, global accounts such as T-cell account would not be sensitive to changes because of the adaptive equilibrium among the different subsets. Similarly, salivary measures such as sIgA are related to the salivary flow. The flow changes in response to stressors so those measures instead of blood samples add another methodological problem to the PNI studies that must be controlled. Otherwise data interpretation might be biased.

Furthermore, enumerative assays provide no information about the functional efficacy of the cells so that type of assays is not very useful, particularly with healthy subjects.

Functional Assays

Functional assays provide information about the 'performance' (Kiecolt-Glaser & Glaser, 1995: 216) of the immune cells. As several authors have pointed out, functional assays are much more informative than enumerative and provide more reliable measures for PNI studies, especially for stress studies. They might be divided into *in vitro* and *in vivo* assays. Among *in vitro* assays, blastogenesis, NK cell activity and latent herpesvirus antibody titres are common. Other *in vitro* assays are viral vaccine antibody titres and cytokine production.

Blastogenesis

Consists of the proliferative response of both T- and B-lymphocytes to stimulation by mitogens such as phytohemagglutinin (PHA) which stimulates T-cell proliferation, pokeweed mitogen (PWM) which stimulates both T- and B-cell division, lipopolysaccharide (LPS) which stimulates B-cells, and concanavalin A (ConA), another T-cell mitogen. These mitogens have the ability to stimulate lymphocytes so that the procedure provides a model of the body's response to challenge by infectious agents. As Kiecolt-Glaser and Glaser (1995) wrote, blastogenesis is one of the few immunological assays reliably associated with relevant health parameters, such as immunodeficiency conditions including AIDS and other illnesses. Lymphocyte proliferation in response to mitogens has been used as a dependent variable in many PNI studies which have tested the effects of stress.

NK Cell Activity

NK cells play a crucial role in tumour vigilance. The efficacy of these cells to lyse or destroy target cells is another way of measuring immune function.

Latent Herpesvirus Antibody Titres

The immune system has 'memory', so once the organism has been exposed to an infectious agent it is able to quickly respond and destroy the pathogen in successive reexposures. However, several viruses are able to hide in a latent state within certain host cells. Herpesvirus is one of them. They have also a very high prevalence (particularly HSV1). The competence of the cellular immune system is thought to be critical in controlling the virus latency. Thus, the increase of herpesvirus antibody titres suggests a less competent control over the virus by the immune system.

T-Cell Responses to a Viral Vaccine

Similar to above, the antibody response to specific infectious challenges such as viral vaccine might be a measure of the competence of the immune system. Counts of antibody titres for viral vaccines such as flu vaccine, common cold, HbsAg, and a novel antigen has been used for that purpose.

Production of Cytokines

Even though only a few studies have used this kind of measure (see Biondi, 2001 for a review), the production of cytokines (particularly IL-4 and IL-6) is another measure of the immune function.

Natural Immune Activity

Non-specific mechanisms against pathogens such as phagocytosis can also be measured as an estimation of immune function. Particularly, two groups of measures can be obtained: functionality of granulocytes (such as adherence, chemotaxis, attachment, and lysis), and phagocytic activity of monocytes and macrophages.

For obvious reasons, *in vivo* assays are infrequent in PNI human studies. Nevertheless, a few of them have used this kind of measure, particularly skin tests.

Skin Tests

The delayed hypersensitivity response to an antigen (usually, tuberculin administered by subcutaneous injection) can be used as an estimation of the functioning of the immune system. In such cases the decrease of the skin reaction (in terms of oedema and skin swelling) shows a decrease in the immune competence.

THE ASSESSMENT OF HEALTH STATUS AND DISEASE

Measures of health status and disease in this context can be separated, at least, into two categories: signs and symptoms (Cohen & Williamson, 1991). Signs are observable. For instance, lesions, fever, rashes and swelling. Symptoms are not observable but reported by the patients. For example, headache or stomach ache. A third group can be added, which is related to the use of health care services, the school and/or job absenteeism, and so on.

Signs

At the present state of knowledge, main areas of potential clinical interest in PNI are cancer, infectious autoimmune diseases, inflammatory bowel disease, multiple sclerosis and wound healing (Biondi, 2001). All these cases allow trained clinicians (using technological aids if needed) to register parameters such as the length of a tumour in cancer, the joint inflammation in rheumatoid arthritis or the occurrence of oral lesions in infection due to HSV.

Symptoms

Non-observable but self-reported variables such as joint pain in rheumatoid arthritis or weakness and malaise under influenza infection have also been used in PNI studies. Nevertheless, although these reports may reflect underlying disease conditions, they may also reflect influences of stress on cognitive processes and self-perceptions that are not associated with the disease. Thus, it is methodologically crucial to avoid unverified self-reported symptom protocols as the only criterion for disease and to validate them.

Seeking for Health Care and Other Outcomes

The number of hospitalization days, the number of medical attendances, the number of absenteeism days, the pharmacological compliance and so on

have been used as a measure of the health and disease status in several PNI pieces of research.

FUTURE PERSPECTIVES AND CONCLUSIONS

In summary, PNI assessment combines objective measures about immune function with health and disease outcomes. These assessment instruments and methods has been mainly imported from other disciplines and they have allowed a steady improvement of the methodological quality of PNI studies.

As an interdisciplinary field, PNI is fed by the related disciplines and its growth in the last years has been spectacular. Further developments in PNI will probably improve the knowledge about immune–neuroendocrine interactions. Therefore, some of the objective measures mentioned above (particularly, cytokines) will increase their importance and some others will arise. Likewise, a better understanding of the illness behaviour as well as the technological development would improve health and disease measures.

Nevertheless, we can predict some constraints in this field which will not be easily overcome. On the one hand, the problem of the 'very best' immunological assay research paradigms many editorials and international meetings have advocated; probably, as Keller, Schiflett, Schleifer and Bartlett (1994) have pointed out, the appropriateness of a measure depends on the experimental design. Moreover, factors such as availability, convenience, or costs will determine the election of one or another assessment method.

On the other hand, the ethical limitations human studies have; regarding humans, in most of the cases the only tissue PNI studies sample is peripheral blood. Secretions such as urine or saliva are available as well. But these allow the study of a very small fraction of the immune system; one of its characteristics is the complexity of its interactions. Furthermore, people's lives go by in natural context in which they rest and argue, smoke and exercise. That is, far from the control such studies try to carry out. According to Keller et al. (1994: 228), 'understanding the product [psychoimmunology] of these two domains [immune system and behaviours and emotions] is likely to be complex'.

Perhaps, as Biondi (2001: 190) wrote, 'one might also wonder if, at this phase in the evolution of PNI, redundant methodological rigour could in some instances, restrain further developments and downplay serendipitous findings, inhibiting innovative and divergent views, while permitting only refinements of already established paradigms'.

PSYCHOPHYSIOLOGICAL EQUIPMENT AND MEASUREMENTS

INTRODUCTION

Psychophysiology is the scientific discipline devoted to the study of the interrelationships between the physiological and psychological aspects of behaviour. Such relationships have preoccupied philosophers and scientists throughout history. The different debates about the soul–body, spirit–matter, or mind–brain relationships are all variations on a single theme: the connection between behaviour – our acts, thoughts and feelings – and its sustaining biological body.

The scientific study of the physiological and psychological aspects of behaviour can be approached through different perspectives. The psychophysiological perspective emphasizes the use of physiological measurements to understand the psychological processes underlying behaviour (Turpin, 1989). The focus of psychophysiology is the non-invasive recording of peripheral and central physiological changes while subjects behave under controlled conditions. This approach has mainly used, although not exclusively, humans as research subjects.

The basic assumption of psychophysiology is that the psychological processes of perception, attention, memory, learning, motivation, emotion, and so on are reflected in the efferent physiological changes – the logistic and instrumental precursors of behaviour – as well as in the physiological brain activity. The psychophysiological methods, therefore, are like windows over the living body – muscles, glands and brain – allowing the knowledge of the complex mechanisms controlling human behaviour.

THE ELECTRONIC AND COMPUTER REVOLUTION

Almost all physiological recording methods are based on the bioelectrical nature of the living tissue activity. Therefore, since the discovery of electricity and its basic principles by the end of the 18th century, physiological recording has evolved in parallel with technological evolution. The first psychophysiological instruments were based on the *galvanometer*: a moving coil suspended in the magnetic field of a permanent magnet that rotates when an electric current flows through the coil. This device, used with any writing system mounted on the moving coil, is the basis of the traditional polygraphs. It allows the detection and measurement of changes in small currents as a function of time.

The moving coil galvanometer was instrumental for the discovery of the main psychophysiological variables: electromyography by Matteucci and Du-Bois Reymond in the middle of the 19th century, electrodermal activity by Vigoroux and Ferè in 1888, electrocardiography by Einthoven in 1900, and human electroencephalography by Berger in 1929. The first electronic circuits used valve condensers, diodes and triodes to filter and amplify the bioelectrical signals. These electronic components were too big, not very precise, and used a lot of energy. In the 1940s a new electronic age began with the discovery of *semiconductors* and the *transistors* – solid state electronic components – opening the race for miniaturization and speed. In the 1970s the *integrated circuits* added the possibility of bringing together complex electronic circuits, equivalent to many condensers, diodes and transistors, into a single unit: the chip.

Psychophysiological instruments have benefited from this electronic revolution in three basic aspects. Firstly, by increasing precision and reducing size and weight of the amplifiers. Secondly, by improving the traditional recording systems using the digital computers to represent, store and analyse the psychophysiological signals. This is done through analogue-to-digital converters interfacing the physiological recording output to the computer. And finally, by permitting the discovery of new psychophysiological variables, only available after complex computerized systems

have been applied to detect and extract the biological signals. This is the case of the new psychophysiological techniques for recording brain activity: event-related potentials, brain electrical activity mapping, magnetoencephalography, positron emission tomography, and functional magnetic resonance imaging.

PERIPHERAL INSTRUMENTS AND MEASUREMENTS

Psychophysiological techniques are commonly classified as peripheral and central ones according to the type of neurophysiological mechanisms directly controlling the physiological activity recorded (see Table 1). Peripheral techniques include those variables directly controlled by the somatosensory nervous system and the autonomic nervous system. Central techniques include those variables directly controlled by the central nervous system. In this section we summarize the main psychophysiological technique belonging to the peripheral somatosensory system – surface electromiography – and concentrate on the main technique belonging to the peripheral autonomic nervous system – cardiovascular activity. The reader interested in other peripheral techniques – electrodermal activity, pupillary system, respiration, eye movements, gastrointestinal system, sexual response system – can consult any of the following handbooks of psychophysiology: Coles, Donchin and Porges (1986), Cacioppo, Tassinary and Berntson (2000), Greenfield and Sternbach (1972).

Surface Electromiography

The biological basis of electromiography is the electrical activity of the striated muscle, the type of muscle responsible for skeletomotor activity and made up of a large number of parallel cells or fibres. This electrical activity is due to the depolarization of the fibre's membrane: changing from positive outside to negative and returning to positive. Such activity is triggered by the activation of the motoneuron which innervates the fibre at the end plate location. The depolarization of the membrane, called action potential, makes the fibre contract by sliding the fibre's inner filaments. Each motoneuron innervates a number of fibres within a muscle, and

Table 1. Classification of psychophysiological techniques with examples of assessment applications

Neurophysiological mechanism	Psychophysiological techniques	Assessment applications
Somatic Nervous System	Surface Electromiography (EMG):	Arousal
	Direct EMG	Facial expression
	Integrated EMG	Motor reflexes
		Relaxation
		Biofeedback
Autonomic Nervous System	Cardiovascular Activity:	Attention
	Electrocardiogram (EKG)	Emotion
	Impedance cardiography	Defence
	Photoplethysmography	Stress
	Blood Pressure recording	Anxiety
	Electrodermal Activity	Stress related illnesses
	Pupillary Activity	Biofeedback
	Gastrointestinal Activity	
	Others	
Central Nervous System	Electromagnetic Techniques:	Arousal
	EEG	Wakefulness
	Event Related Potentials (ERP)	Sensory processes
	Brain Electrical Activity Mapping (BEAM)	Cognitive processes
	Magnetoencephalography (MEG)	Movement preparation
	Metabolic Techniques:	Brain mechanisms
	Positron Emission Tomography (PET)	Brain reorganization
	Functional Magnetic Resonance Imaging (fMRI)	Psychopathology

each muscle fibre is usually innervated by only one motoneuron (Tassinary & Cacioppo, 2000). This functional physiological entity, made up of a single motoneuron and the individual muscle fibres innervated by the motoneuron, is called the *motor unit*.

Recording of the action potentials of the striated muscles from the surface of the skin receives the name of surface, electromiography (EMG). This EMG signal represents the ensemble of action potentials produced by the muscle at a given moment. The aggregate signal is characterized by a frequency range – between 20 and 1000 Hz – and an amplitude range – between 2 and 2000 microvolts – such that a direct relationship between frequency and amplitude exists: the greater the frequency the greater the amplitude. Accurate recording of the surface EMG requires careful attention to electrode site preparation and placement, grounding, noise reduction, and differential preamplification (see Tassinary & Cacioppo, 2000).

In psychophysiological studies it is common to transform the direct surface EMG into integrated EMG. The integrated EMG signal is the arithmetic average of the rectified and smoothed EMG signal. This is normally done by electronic circuits within the preamplifiers, although a similar transformation can be obtained by digital filtering. The integration procedure implies, firstly, rectification of the signal – elimination of the negative mirror part of the signal – and, secondly, smoothing of the remaining signal by a low-pass filter. This produces a contour following integration: a varying voltage proportional to the envelope of the direct EMG signal.

Measurement of the integrated EMG gives a simple index of total energy in the muscle at a given moment. This type of index has been used in many psychological research contexts: to measure activation or arousal, facial expressions, somatic correlates of thought and imagery, motor reflexes, etc. The technique has also been useful in many applied contexts: relaxation and stress reduction, physical rehabilitation, ergonomics, detection of deception, and polysomnography, among others. An example of integrated EMG measurement is the startle probe paradigm. Startle is a motor reflex elicited by abrupt stimulation. In human beings, rapid eye closure is one of the most reliable component of the behavioural reactions that constitute the startle reflex (Bradley, 2000). Measurement of the reflex magnitude is done by recording the integrated EMG of the orbicularis oculi, the muscle around the eye, and by scoring its EMG response amplitude. The startle probe paradigm is used to study the modulatory effects of psychological processes on the reflex magnitude: emotional and attentional priming or inhibitory effects.

Cardiovascular Activity

The cardiovascular system consists of a pump – the heart – and a network of vessels – arteries, arterioles, capillaries, venules and veins – for distribution, exchange and return of the blood throughout the body. This system fulfils the main vital function of the organism: to guarantee the necessary energy supply to all body cells in order to keep them alive and efficient in their activity. The cardiovascular system reacts rapidly to physical and psychological demands. Such reactivity is mainly controlled by neural and humoral pathways.

The *neural pathway* to the heart involves the two branches of the autonomic nervous system: the sympathetic and the parasympathetic. When the sympathetic nerves are activated the heart rate accelerates and the heart contraction becomes stronger, resulting in a greater blood volume discharge and greater blood pressure in the vessels. When the parasympathetic nerves are activated the heart decelerates, reducing the blood volume discharge and the blood pressure. The neural pathway to the vessels mainly involves the sympathetic nerves, its activation producing either vasoconstriction or vasodilation depending on the type of sympathetic receptors in the vessels: sympathetic receptors predominant in skin and viscera vessels produce vasoconstriction whereas sympathetic receptors predominant in skeletomotor vessels produce vasodilation. The *humoral pathway* involves the neural sympathetic activation of the endocrine system, resulting in the secretion by the adrenal glands of various hormones into the bloodstream. One of these hormones, or adrenaline/epinephrine, when it reaches the heart and the vessel receptors, has similar effect as the direct sympathetic activation: it increases the heart rate, the stroke volume, and the vasomotor activity constriction or dilation depending on the vessels. Other adrenal hormones, like cortisol, facilitate the transfer of

lipids and glucose into the bloodstream. The humoral effects on the cardiovascular system are slower than the neural ones but they last longer, contributing to maintaining cardiovascular reactivity during prolonged periods.

To examine the impact of psychological processes on cardiovascular reactivity requires reliable non-invasive measurements of the different components of cardiovascular activity. Cardiac function is assessed through three indices: *heart rate* – number of ventricular contractions per minute – *stroke volume* – the amount of blood pumped from the left ventricule in each contraction – and *cardiac output* – the product of stroke volume × heart rate. Vascular function is assessed through two indices: *blood pressure* – the force of the circulating blood in the arteries – and *blood flow* – amount of circulating blood in a particular area.

In psychophysiological studies, heart rate is the main index to assess cardiac function. Heart rate is measured in terms of beat-by-beat heart rate changes derived from the *electrocardiogram*. The cardiac period – interval in milliseconds between consecutive R waves of the electrocardiogram – is detected by the computer and transformed into heart rate: heart rate = reciprocal of cardiac period × 60,000. Using a weighted averaging method, heart rate is then transformed into second-by-second – or any other time epoch – heart rate. Other indices of cardiac function – as stroke volume or respiratory synus arrhythmia – are normally used to differentiate sympathetic versus parasympathetic influences on the heart rate. As regards vascular function, one of the most frequently used indices is blood volume amplitude. A relative measure of vasomotor activity – constriction and dilation – can be easily obtained through *plethysmography*, a device to measure limb changes in blood volume. Photoplethysmography is a simple method to record blood volume amplitude on a beat-by-beat basis that can also provide information on heart rate similar to the electrocardiogram.

The central nervous system controls cardiovascular functioning through a complex network that includes cortical structures – prefrontal cortex, anterior cingulate – subcortical structures – amygdala, hypothalamus – and hindbrain structures – ventrolateral medulla, nucleus ambiguus, nucleus tractus solitarius. Through this network, cardiovascular reactivity plays an important role in cognitive and emotional processes, as well as in stress and cardiovascular-related illnesses. Several psychophysiological paradigms have been used to assess these normal and pathological processes: the orienting-defence (Sokolov, 1963; Graham, 1979), the intake-rejection (Lacey & Lacey, 1970), and the active–passive coping (Obrist, 1981) paradigms. They measure phasic and/or tonic cardiovascular responses during psychological tasks. The heart rate response and heart rate variability have been the two cardiac parameters most frequently used. The heart rate response to moderate/intense stimulation – for example, a brief white noise – or to affective pictures shows a complex pattern of accelerative/decelerative changes interpreted as indicative of attentional and/or emotional processing. Heart rate variability, on the other hand, is an index of parasympathetically mediated cardiovascular control that serves to inhibit sympathetic influences. A relative reduction in cardiac variability has been interpreted as indicative of increased mental stress and ineffective emotional regulation and has been found associated with symptoms of cardiac and emotional disorders.

CENTRAL INSTRUMENTS AND MEASUREMENTS

Technological advancements have been fundamental for the development of the new brain activity recording methods: the functional neuroimaging techniques. The instruments to measure central nervous system activity are classified into two general categories: electromagnetic and metabolic techniques (see Table 1). The electromagnetic techniques are based on the electrical activity of the brain tissue: the neurons' action potential. This electrical activity can be detected non-invasively either in the skull in the form of voltage changes, using surface electrodes, or around the skull in the form of magnetic field changes, using electromagnetic sensors. The metabolic techniques are based on the differential distribution of blood elements – mainly oxygen and hydrogen – in the brain. Since neurons require these elements to produce their action potentials, the differential blood concentration in the brain is assumed to be an indirect index of the brain activity.

Electromagnetic Techniques

Electroencephalography (EEG) was the first electromagnetic technique developed. Since Berger's first report in 1929, EEG recording improved during the 1930s and 1940s. In 1949 the launching of the journal *Electroencephalography and Clinical Neurophysiology* resulted in the full recognition of EEG as a reliable technology for recording brain electrical activity as an integrated neurophysiological phenomenon relevant to assess psychological processes such as arousal or wakefulness. EEG recording requires, as all psychophysiological techniques, careful attention to electrode location, minimum number of electrodes needed, choice of electrode reference, grounding, proper filtering and artefact control. A good EEG recording is characterized by changes in voltage as a function of time with two basic descriptive parameters: frequency and amplitude. These two parameters are inversely related: the greater the amplitude the lower the frequency. The lowest frequency band (0–4 Hz) – called delta range – has the greatest amplitude (20–200 microvolts), and the highest frequency band (36–44 Hz) – the gamma range – has the lowest amplitude (2–20 microvolts). The intermediate frequency bands – theta (5–7 Hz), alfa (8–12 Hz), and beta (13–30 Hz) ranges – have a progressively decreasing amplitude.

An important technological development based on the EEG occurred in the 1960s with the advent of digital computers. EEG recording focuses on spontaneous rhythmic fluctuations in voltage: the frequency ranges. Specific EEG responses to events are obscured by the larger background EEG fluctuations. Digital computers enabled the extraction of the event-related brain activity from the background EEG by applying the averaging procedure: to repeat a particular event and average the digital samples of the EEG that are time-locked to that event. This procedure increases the discrimination of the 'signal' (the ERP = Event Related Potential) from the 'noise' (the background EEG). The resulting signal contains a number of positive and negative peaks identified by the letters P or N with a numeric subscript (1, 2, 3, 4 or 100, 200, 300, 400) which indicates, respectively, the order or time in milliseconds of the peak. Once extracted, ERPs are interpreted as manifestations of the specific psychological processes activated by the event.

In the 1990s new technological advances allowed new recording techniques of electromagnetic brain activity: dense electrode array, brain electrical activity mapping, and magnetoencephalography. Traditional EEG and ERP techniques were limited to a reduced number of channels (up to 32). The recent increase in the number of recording channels (up to 256) has facilitated the study of the spatial distribution of ERP activity across the scalp, allowing the construction of accurate maps of the surface brain electrical activity. In addition, dense electrode array has allowed the generation of mathematical models for three-dimensional location, within the brain, of the source of the surface ERP activity. This has been supplemented with the advent of the latest technological development: the magnetoencephalography (MEG). This technique records the small magnetic fields generated around the scalp as a consequence of the electrical brain activity. It can provide similar information to ERP techniques but, in addition, allows precise identification of the brain generators of the surface ERP activity by means of identification of magnetic dipoles: two equal but opposite magnetic fields separated by a small distance.

The electromagnetic techniques are, at present, one of the best methods, in terms of temporal resolution, among non-invasive neuroimaging techniques. The advantage of these techniques is the time course of the signal which permits resolution in the millisecond domain. As psychological processes change dynamically over short periods of time, the electromagnetic signal is ideal for linking ongoing changes in neuronal activation with ongoing changes in behaviour.

Metabolic Techniques

The main limitation of the electromagnetic techniques is their poor spacial resolution: inability to examine brain function in an anatomically precise way. The electronic and computer revolution of the past few decades has permitted the development of more precise techniques for visualization of brain function based on metabolic changes. These techniques are, in some way, similar to traditional radiological techniques, like X-ray and Computerized Tomography (CT). The image construction is based on the recording of radiological signals emitted by moving blood particles in

the brain – oxygen and hydrogen – necessary for neuronal activity.

The first metabolic neuroimaging techniques developed were the radiotracer techniques. *Positron Emission Tomography* (PET) is one of them. The radiotracer commonly used in PET is a pharmacological compound labelled with a positron emitting radioisotope – O^{15} – of short life – around 4 to 10 minutes. Once administered to the subject, either intravenously or by inhalation, the radiotracer is distributed through the blood to all parts of the body, including the brain. The radiotracer starts decaying inmediately due to the emission of positrons: subatomic particles within the nucleus with positive charge. The number of emitted positrons detected from outside the head reflects the amount of oxygen demand in the different brain areas, indicative of their neuronal activity. Using computerized tomographic methods, the PET system can produce bi-dimensional sliced images of brain activity in any inner plane of the brain.

The main problem with PET and other radiotracer techniques is the possible risk of lesions due to radiation. The most promising alternative to date, also based on neuronal metabolism, is *functional Magnetic Resonace Imaging* (fMRI). The physical foundations of fMRI are the magnetic properties of certain subatomic particles – the spinning protons within the nucleus – that behave as small magnetic needles. The technique uses this magnetic property of the hydrogen nucleus, an element abundant in the body. When the body is placed within the magnetic field of a potent external magnet, all hydrogen protons line up along the axis of the external magnet. The orientated spinning protons, in addition to spinning around their own axis, also rotate or *precess* about the axis of the external magnetic field with a rotating frequency that is within the range of radiofrequency waves. The MRI technique then introduces, using a transmit–receive coil, a momentary external radiofrequency wave perpendicular to the magnet axis and identical to the precessional frequency of the spinning hydrogen protons to produce the resonance phenomenon: the axes of the spinning protons change their alignment, returning slowly to their original position when the external radiofrequency is turned off. This slow return of the spinning protons to the direction of the external magnetic field generates a decaying electromagnetic signal that is detected by the receive coil. This is the signal used by the fMRI system to create the image, since the magnitude of the received signal is directly proportional to the amount of hydrogen atoms in the tissue: the greater the signal the greater the metabolic neuronal activity.

FUTURE PERSPECTIVES AND CONCLUSIONS

The new psychophysiological techniques of brain activity have opened up new possibilities for psychological research and application, including psychological assessment. Indeed, almost all areas of psychology have started to introduce these new variables either as substitutes or complements of more traditional dependent variables, such as reaction time or percentage of hits and errors. They provide on-line information of the internal mechanisms mediating stimulus–response relationships confirming or disconfirming the many inferences made by psychology on the inner processes that regulate and direct behaviour. But the new technologies have also brought in new problems that future developments will have to solve. One of these problems is incompatibility among psychophysiological techniques. Functional Magnetic Resonance Imaging, for example, is currently incompatible with electromagnetic and peripheral techniques, due to the interfering external magnet. Another problem is the poor temporal resolution of the metabolic neuroimaging techniques and the poor spatial resolution of the electromagnetic techniques. These problems point to the need for future technological improvements to allow convergence and complementarity between different psychophysiological methods, as well as between psychophysiological and behavioural measurements.

QUALITATIVE METHODS

INTRODUCTION

Qualitative assessment represents a particular methodological paradigm. A paradigm can be viewed as a system of inquiry marked by distinctive epistemological foundations, corresponding conceptual assumptions, and characteristic methods and modes of procedural practice. This entry discusses those ideological foundations, considers their assumptions, and traces their translation into the procedures and practices that jointly constitute qualitative assessment.

Qualitative methods (summarized in Table 1) are frequently described in contrast with quantitative methods. This distinction simultaneously sharpens and blurs distinctive features of each. By drawing attention to the preference of the former to attend to *qualities* of experience that extend beyond, or transcend, the *numerical indexing* that predominates in the latter, this distinction highlights their differences at the level of operations or outcomes. But this distinction has limitations, and the line is not always clearly drawn between them. For example, Jessor has observed that 'qualitative data lend themselves to be quantified and quantitative data can be interpreted' (1996: 6). Given this qualification, however, a number of distinctive features have been associated with qualitative forms of assessment, and these features follow from its distinctive epistemological commitments (Denzin and Lincoln, 2000).

FOUNDATIONS AND FEATURES

Key differences between quantitative and qualitative approaches follow from fundamental epistemological differences that, in turn, translate into different approaches to the development, utilization, and interpretation of data derived from these methods.

Foundations

The social sciences are broadly regarded as multiparadigmatic. This amounts to acknowledging that there is no single agreed-upon set of theories or methods that define them. Psychology, in particular, enjoys a range of approaches derived from the natural, social, and human sciences. In drawing a distinction between *quantitative* and *qualitative* methods, researchers and practitioners highlight a dimension that distinguishes methods on the basis of their epistemological assumptions. Quantitative approaches subscribe to the epistemological assumptions of the natural sciences. This view, that the objective study of observable variables is adequate to produce knowledge

Table 1. Examples of qualitative assessment techniques, instruments or methods

Technique, instrument or method (creator, when known)	Description	Main purpose(s)	Applications	Advantages	Disadvantages or limitations	References
Observation	A systematic description of events, behaviours, speech and artefacts in the naturally occurring setting.	Depends on the setting: it is the most popular technique in everyday life and the first step in inductive methods.	Some forms or elements of observation are always present in any research method.	• Applicable in ecological settings (naturalistic observation) • Flexible and adaptable to different situations • Open-ended and propositional • Can be used with other techniques, taking into account several variables • Can accommodate possible technological devices • Access to information that is usually hidden, as non-verbal cues	• Its use may bring ethical issues • Differently from most of the other qualitative approaches, 'findings' can be divorced from the experiential knowledge of those being observed • In naturalistic settings the observer affects the observed, changing behaviours in subjects of study (see 'Participant observation') • Sometimes difficult to interpret • Time-consuming	Bannister, P. et al. (1994), Chapter 2; Angrosino, M.V. & Mays de Pérez, A. (2000)
Participant observation (Malinowski, 1922)	Observation in which the researcher also occupies a role or part in the setting, in addition to observing. It combines: document analysis, interviewing of respondent and informants, direct participation and observation, and introspection. Three phases: 1 Descriptive observation 2 Focused observation 3 Selective observation	Understanding natural interactions and interpretations.	The same domain of application in observation (above). Mainly used in ethnography, education and research on social issues.	• Focus on meanings, interactions and understanding • Here and now of the everyday life situations • Open-ended, flexible, opportunistic • Adaptable to on-going, ever changing processes	• Limitation in the observer's observational perspective • Ethical issues • Need to 'go native': researcher's personal insights on the subject of study • Need for familiarity, psychological contact to and understanding of the subject	Flick, U. (1998); Jorgensen, D.L. (1989)

Ethnography	A multi-method form of research that involves participant observation, interviewing, narrative analysis, among others. Based on the sympathetic understanding and interpretation of a particular social phenomenon ('to go native'). It works primarily with unstructured data.	Social scientific description of people and the cultural bases of their personhood. Study of natural settings ('field research'), cultures, meanings and values.	Anthropology, sociology, social psychology, education.	• Multi-method approach • Attempt to understand the effects of the active participation of the researcher in the study • In-depth study of meanings in order to sympathize with the subject of study • Adaptable to different circumstances (open and flexible)	Investigation is limited to a reduced number of cases, usually one or two. Limited possibility of planning the research. Dependent upon the researcher's skills in each situation.	Bannister, P. et al. (1994, Chapter 3); Jessor, R. et al. (1996); Tedlock, B. (2000)
Focusing (Gendlin, 1978)	Technique for directing person's attention towards bodily targets, in order to increase feelings of personal wholeness, linking bodily sensations to personal experiences.	Overcome the split between body and mind.	Humanistic, experiential psychology and psychotherapy.	Helping clients access their experience by having them attend to and symbolize their bodily felt sense.	• Enhances emotional awareness • May amplify distress or dissociation • Requires minimal levels of cognitive and emotional processing	Gendlin (1978)
Repertory Grid (Kelly, 1955)	Elicitation and analysis of personal constructs (rows) applied to elements (columns).	Better knowledge of system organization through construct placement and relationships in the psychological space.	Clinical, counselling and personality psychology. Wherever it is important to identify and clarify the idiosyncratic dynamics of values and meanings.	Constructs can be either personally elicited or provided, permitting the comparision of different repgrids. Repertory grids can be analysed using software program.	The elicitation procedure can seem complicated. There is the risk for constructs and their relationships to be reified by the analyser, therefore forgetting the original constructivist conception of constructs as idiosyncratic, contextualized, inter-related, and dynamic descriptions of the person's 'invented' reality.	Fransella, F. & Bannister, D. (1977)

(*continued*)

Table 1. Continued

Technique, instrument or method (creator, when known)	Description	Main purpose(s)	Applications	Advantages	Disadvantages or limitations	References
Self-characterization (Kelly, 1955)	Self-description of the individual as the protagonist of a play. The draft is written in the third person by the individual as if s/he were being described by a hypothetical other who knows him/her very well.	To obtain the narrative description of the way the person is presenting her/himself.	Counselling and personality psychology, adult development and education, vocational psychology.	Easy to obtain. It allows clients to go beyond their initial concerns, describing themselves in a broader way.	• Generates a 'perspective shift' on part of the user • Engaging and informative • Can invite self-reflection and (re)construction	Fransella, F. & Dalton, P. (1990)
Vocational Card Sort (VCS) (Tyler, 1961; Dewey, 1974)	Semi-projective method: individuals project onto a set of cards with occupational titles their idiosyncratic classifications of occupations	Exploring idiosyncratic work interests, values, needs and goals for groups and/or individuals.	Vocational counselling, education.	• Can be used both for individuals and groups • Simple to administer • Categories produced are idiosyncratic and therefore individuals are not forced into a present limited framework • Flexibility • Multicultural applicability and adaptation • Individuals are full participants in the assessment process	• Requires individuals who are able to abstract and generalize • Is most useful in groups with very different work goals and different interests and needs	Goldman, L. (1983, 1992)
Friendship Inventory	On a sheet, the individual writes the name of each friend and for each, the person's age, ethnic identity, skin colour, marital status, religion, occupation, how long known, and other categories that the assessor wants to add.	To highlight major narratives in one's life, regarding social aspects and personal identities.	Counselling, education.	• Flexible and adaptable to the particular individual or group • Usable with people from different ethnicities and/or cultures	It is most useful with heterogeneous groups	Goldman, L. (1996)

				• Highlights cultural and social diversity • Great stimulus for group discussions • Easy to translate in other languages		
Certificate of Accomplishment	Participants are asked to place themselves at some point in the future and to assume that they have been selected as a recipient of a very special and important achievement. Individuals are asked to write the statement in the certificate.	Stimulate people to fantasize and project their important values and goals.	Individual and group counselling, education.	• It offers a special opportunity to reveal personal cultural differences about ambitions, expectations, perceived barriers, biases or racism	• Some cultures (i.e. Asian or Native American) may consider it is inappropriate to focus on one's personal accomplishments or ambition	Goldman, L. (1996)
The Life Line	The individual displays graphically on a sheet of paper the major events in her or his own life, with an indication of their effects on the person's current and future condition, feelings or status.	To help people to review their life histories and personal narratives. Increase awareness of their values, needs and factors that have contributed to their development and current status.	Individual and group counselling.	• Provides a development framework of the person • Enhances self-awareness and growth • Adaptable to almost every cultural or ethnic group • People provide their own structure, selections and categorization of events	• It risks giving events a linear causality, but helps to identify trends, themes or overall developmental trajectory for the person	Goldman, L. (1992, 1996)
The indescribable moment (Neimeyer, G.J., 2000)	A constructivist assessment technique involving interaction among two or more individuals that is designed to access a client's distinctive emotional and linguistic representational abilities.	• Identifying emotional and linguistic representational abilities • Encouraging reflection and reconsideration of powerful emotional experiences	Mainly used in group therapy, clinical training, and adult education and development contexts.	• Applicable in individual, couple, family, or group therapy contexts • Flexible and adaptable; invitation to 'consider any important experience that you have had that is hard to put into words for you', has broad range of applicability	• Relies on a capacity and context that assures trust • Requires willingness to suspend 'interpretation' in the interest of promoting 'discovery'	Neimeyer, G.J. (2000)

(*continued*)

Table 1. Continued

Technique, instrument or method (creator, when known)	Description	Main purpose(s)	Applications	Advantages	Disadvantages or limitations	References
		• Highlighting the dialogical nature of the construction of meaning. Allows for the identification of primary modes of representation (linguistic, metaphorical, etc.) and invites experiential deepening beyond currently available cognitive constructions.		• Enhances cohesion, emotional deepening, and effective working alliance in individual, family or group contexts • Accesses aspects of emotional experience not otherwise available in 'cognitive' accounts, and reveals idiosyncratic forms of representing them	• Careful description of experience can re-invoke that experience; for traumatic experiences this 'revivification' can be powerful and potentially threatening, even as it yields new possibilities for the deconstruction or reconstruction of the experience	
Interview	Characteristics that are common to different kinds of interview: • Emphasis on subjective meanings of the participants according to the topic of the interview • Investigating complex meanings and their relationships • Focus on specific areas of concern	Through a certain level of personal involvement and through interactions with interviewee(s), interviewers identify idiosyncratic meanings or world views that describe the individual or the group experiences.	Some forms or elements of interview are present in any research method	• Flexible • Attention to personal and specific issues raised by the interviewee • Do not tend implicitly to reduce or simplify meanings • Permits the understanding of views that may be inconsistent, incoherent or illogical to the interviewer	• Dependent upon the interviewer's skill and expertise • Risk for the interviewer to play a powerful role in the research relationship. As a consequence, there is a clear need for reflexivity: researchers have to reflect on the purposes of the interview and on a set of power relations such as class, race, ethnicity, gender, age, etc.	Kuale (1996)

					• It may not be suited to interviewees who belong to or identify with cultures that do not consider verbal language as a primary tool of communication	
1	Structured interview: the interviewer asks all respondents the same series of pre-established questions, often with specific rules about the order and the selection of the questions, which depends on the person's response to previous questions.	Broad type of contents	Marketing research, telephone interviews, interviews associated with survey research.	• It is not necessary to establish a relationship or to be involved with the interviewee(s). Being the most quantitative kind of interview, researchers may be attracted by specific features, as the possibility of studying single variables, the causal and logical model, the goal of controlling, predicting and confirming hypothesis, the deduction by statistical methods.	• Limited room for variation. Little flexibility and improvisation • Responses are coded according to already established criteria • Attempt to limit personal variation and interpretation related to the research relationship • Risk of response effects or non-sampling errors • Usually does not assess the emotional and more idiosyncratic dimensions	Fontana, A. & Frey, J.H. (2000)
2	Focused interview (Merton, R.K. & Kendall, P.L., 1946): interview about the impact of a specific topic that works as stimulus.	Analysis of subjective meanings.	Media research, counselling.	Its initial non-directivity enables personal expressions, and it reduces the imposition of the interviewer's frame of reference.	It is assumed that the features of the stimulus are objectively known.	Flick, U. (1998)

Table 1. Continued

Technique, instrument or method (creator, when known)	Description	Main purpose(s)	Applications	Advantages	Disadvantages or limitations	References
	3 Semi-structured interview: the interviewer is guided by a schedule of questions or topics, which gives some order and direction to the interviewee's answers. The interviewer is partially free to modify the questions and follow up the person's responses.	Reconstructing and taking into awareness subjective assumptions, knowledge, and interpretation about a specific topic or area.	Counselling, psychotherapy.	Interviewers can tailor their questions to the interviewees' position, issues and comments.	• Deeply based for its implementation and interpretation on the relationship between the interviewee and the interviewer • Difficult mediation between the course of the interview and the interviewer's interests	Bannister, P. et al. (1994)
	4 Unstructured (open) interview: very close to participant observation. In a specific setting, the interviewer interacts with the interviewee with as little direction as possible. The interviewer is free to modify the questions and to follow up on the answers.	To understand complex behaviours and meanings without imposing any a priori categorization.	Ethnography, counselling, psychotherapy, social research.	• Very adaptable to different contexts and cultures, and to unexpected situations • Provides a great breadth of data • Transmits to the interviewee the feeling of deep and genuine acceptance by the interviewer	• It may be difficult or lengthy to have significant information about the topic of interest • It may not be suitable for less-verbal people	Fontana, A. & Frey, J.H. (2000)
	5 Narrative interview: the individual is asked to present the history of an area of interest, in which the interviewee participated, in an extemporaneous narrative.	• To expand or increase the consistency of the personal story about an identified area, from its beginning to its end • To highlight subjective development and coherence	Biographical research, counselling, life review in adult development.	• Allows the researcher to approach the interviewee's experiential world in the way the person presents it • Highlights the structure, the progression and the development of the person's history	• Generates substantial textual material in the transcripts of narrative interviews • The lack of structure may make the recognition of main narratives difficult	Polkinghorne, D.E. (1988); Flick, U. (1998)

6	Group discussion: systematic questioning of several individuals simultaneously in a formal or informal setting, with emphasis on group dynamics.	• Studying of group dynamics in their natural setting, and observing the production, expression, exchange, and negotiation of opinions among members • Analysis of common processes of problem solving in the group	Marketing research, group counselling and therapy.	• Has been used as an alternative to open interviews, with considerable time and money saving • Group discussions provide validating statements and views • A breadth of information from various points of view, with an anticipation of the potential dynamics that may be linked to specific topics or arguments • It may reveal how opinions are created and above all changed, asserted or suppressed in social exchange	• Difficulties in defining what is an optimal group (e.g. natural vs. artificial groups; homogeneous vs. heterogeneous; determining the role of the moderator) • Unpredictable dynamics and outcomes • As for semi-structured interviews, the mediation between the course of the discussion and the research topic may be difficult • Potentially, there may be difficulties in facilitating the development of group dynamics, and the integration of all the participants • Difficulties in comparing data from different groups	Fontana, A. & Frey, J.H. (2000); Flick, U. (1998)
7	Focus group (Merton, R.K., Fiske, M. & Kendall, P.L., 1956). A limited number of homogeneous members discuss a specific topic, within a permissive and non-threatening milieu. Inclusion and use of group interaction.	Data generation from participants' interaction and insights on experiences and beliefs.	Group counselling; marketing and media research; research on social issues (health, sexual abuse, etc.) and multiculturalism;	• Applicable in natural and social settings, typical of everyday life	• Its use is not always appropriate (i.e. when it is necessary to share confidential information). Participants may not feel comfortable with each other.	Morgan, D.L. (1998); Madriz, E. (2000)

Table 1. Continued

Technique, instrument or method (creator, when known)	Description	Main purpose(s)	Applications	Advantages	Disadvantages or limitations	References
		Development of alternative interpretations through meaning discussion and negotiation with other members. Generation of hypothesis.	programme evaluation; development of survey instruments; alternative to test validation (use of the group for finding alternative interpretations of data obtained from other methodological procedures).	• Accentuates empathy, commonality of experience and fosters self-disclosure and self-validation among participants and in that part of the population that can identify with the group. At the same time it emphasizes diversity and differences from discussions and negotiations. Generates awareness and consciousness by developing interactive data and by contributing to the social construction of meaning. • Easy to use with other methods (i.e. observation, personal interviews)	• Difficult to generalize from the research results	Kvale (1996)
	8 In depth interview: the conversation does not use present questions, but is shaped by a defined set of topics or dynamics between the assessor and the interviewee.	Exploring personal and deep issues or topics in detail.	Counselling psychology, psychotherapy.	It allows the exploration of deep idiosyncratic meanings that play a significant and ordering role in the person's system, both psychological and social.	• It requires a good relationship between the interviewer and the interviewee in order to reach a satisfactory depth • Requires expertise by the assessor	

about the structure of reality, remains the predominant one in the behavioural sciences today. In contrast, qualitative methods assume that knowledge is an interactive and emergent phenomena, necessarily grounded in the context, and bounded by the perspectives that gives rise to it. This latter perspective has developed in relation to conceptual shifts within the philosophy of science over the course of the last century.

Nearly a century ago, for example, Max Weber (1906/1949) criticized the positivistic aspiration towards absolute knowledge by situating objectivity in the method(s) of inquiry rather than in the properties of the object or events being studied. By articulating the tacit agreement among 19th century scientists that the object imposes or determines the method, Weber drew attention to the alternative viewpoint that the method and the subject both play roles in the construction of the object. In this way Weber presaged much of this century's development in relation to qualitative assessment. Fundamental to this assessment is a blurring of the boundaries between subject and object, between the knower and the known, highlighting the thorough going interrelationship of each with the other. The focus turns from understanding the independent qualities of an objective, knowable, stable, and universal object, to the contextualized interpretation or co-construction of the events or experience from a particular perspective. According to this viewpoint, scientific inquiry 'is, therefore, no passive copying of reality but is, rather, an active construction or constitution of it' (Madison, 1988: 17).

A number of different typologies have been offered to distinguish among the variety of qualitative paradigms currently in use within the social sciences. Polkinghorne (1984), for example, distinguished among human action inquiry, the systems framework, and qualitative research models as three predominant alternatives to traditional quantitative approaches. Alternatively, Hoshmand (1989) distinguished among phenomenological, naturalistic-ethnographic, and cybernetic paradigms. Specific techniques representative of these qualitative orientations include such strategies as participant-observation, archival research, ethnographic observation, oral history methods, life history or review methods, the qualitative comparative method, or the use of critical incidents or qualitative interviews. Further information concerning these approaches and their distinctive epistemological positions can be found in the work of Madison (1988), Hoshmand (1989), and Taylor, Marienau and Fiddler (2000).

Practical Features

The epistemological foundations of qualitative methods are expressed in a number of common features. These features represent distinctive inflections that are shared, to a greater or lesser extent, by a wide range of qualitative methodologies. These commonalities include similarities in their (a) purpose, (b) roles played by the participants, (c) procedures and processes, (d) data and data analysis and (e) standards of knowledge that are applied to the data generated.

Purpose of Assessment

The purpose of qualitative assessment often centres on an understanding or articulation of meanings. These meanings are understood as co-constructed interpretations that arise out of the interaction between or among participants in the assessment procedure. For this reason many qualitative methods have been called interpretive methods. Their goal is the development of meaningful understandings through the systematic application of personal and social processes that illuminate useful courses of action. By comparison with traditional, quantitative methods, qualitative assessment generally places greater emphasis on description and discovery than on hypothesis testing or verification, per se.

Roles of Participants

The roles of the individuals involved in qualitative assessment can vary widely, but are commonly regarded as more open, reflexive and collaborative than in their quantitative counterparts (Kvale, 1996). Qualitative methodologies place greater emphasis on the researcher as an instrument of inquiry, and encourage the development of a more collaborative, mutual, or dialogical process in relation to the individual being assessed. Participants are regarded as 'co-investigators' in the process of assessment, and they are often consulted regarding the meaning or interpretation of the results. Implicit in this posture is the relative deconstruction of

the power relationship between the participants, and an admission that all outcomes, regardless of the paradigm that yields them, are ultimately human constructions that cannot exist outside of the realm of the interpretive, human process that yields them. In short, there is no 'objectivity', only perspectively embedded interpretations offering varying degrees of consensual validity and/or pragmatic utility. As Polanyi (1958: 3) has noted, 'as human beings, we must inevitably see the universe from a centre lying within ourselves and speak about it in terms of a human language shaped by the exigencies of human intercourse. Any attempt rigorously to eliminate our human perspective from our picture of the world must lead to absurdity.'

Procedures and Processes

The processes and procedures of inquiry are relatively organic or emergent. This process is designed to allow for greater discovery, to encourage unplanned 'backlooping' or re-assessment, and to facilitate decisions to alter the course of the assessment in relation to the data that emerge from it. In short, they entail 'a continuous movement between emerging conceptualizations ... and empirical observations' (Denzin, 1970: 186). Because the process of assessment is continually open to feedback, it discourages premature closure, and instead invites a more mutual and provisional ending to the assessment procedure. Importantly, qualitative procedures can challenge the standardization and uniformity of common quantitative procedures. Because they have a more emergent, unfolding quality, their structure often is more complex, more idiosyncratic, and more fluid. Qualitative procedures place a premium on emergent understandings over procedural uniformity, introducing greater variability into the application or utilization of any given method or assessment technique.

Data and Data Analysis

In contrast to quantitative methods, qualitative methods tend to embrace more contextually 'whole' data, and to adhere less exclusively to a preplanned linear sequence of steps or procedures in their analysis. Many qualitative approaches retain a commitment to holism, preserving the natural categories and context in which the data occurs. One consequence of this commitment is that qualitative data tend to suffer less reduction than their quantitative counterparts which, in turn, invites the intensive study of distinctive features of experience. 'Human psychological phenomena such as anguish, fear, joy, grief, anger, love, sadness, etc' (Ashworth, Giorgi & de Koning, 1986: ix) all become the legitimate object of assessment, as do other phenomena that are not easily reduced to numerical indexing and discrete variables.

Strategies for analysis and interpretation vary widely. Some data analytic techniques are phenomenological and hermeneutic, directed at understanding the intersubjectively shared expressions and/or personal meanings of the participants involved in the assessment. These approaches tend towards what has been called 'thick description' (Geertz, 1973) insofar as they reflect a commitment to inductive observation and rich description. The perspective of the participant receives a position of primacy, and the natural meaning categories used by the participants often replace or expand the predefined theoretical units established by the interviewer or researcher. The *constant comparative method* illustrates one means for analysing this kind of qualitative data. This inductive procedure combines systematic coding with ongoing theoretical formulations. The investigator first codes each bit of data (e.g. sentence, meaning unit, response, etc.) into as many categories as possible. As further categories emerge, the investigator considers possible theoretical properties of the category, its relationships to other categories, and the contexts or conditions under which it is evidenced to a greater or lesser degree. This process requires a continual re-reading of the data and ongoing refinement of the categories and the interrelationship among those categories. The final set of categorization represents a mosaic of meanings, used to construct, support, or revise a theoretical picture of the phenomenon being studied. While 'messy', such thick-descriptive data are likely to be superior to quantitative data in the characteristics that are more important in holistic work than precision and reproducibility (Kvale, 1996).

Criteria of Knowledge

Qualitative strategies share with their quantitative counterparts a commitment to scientific inquiry

and the pursuit of knowledge based on that inquiry. But these methods define this pursuit and its objectives in somewhat different terms. From a quantitative position, truth can be defined according to criteria that address the accuracy of the method in relation to its approximation of reality ('validity'), and its capacity to reproduce its measurement results ('reliability'). The underlying notion is that reality can be approached and revealed through progressive scientific inquiries. Like quantitative methods, qualitative approaches are concerned about making knowledge claims and advances. But, because qualitative methods concede that reality is neither singular nor stable, neither universal nor ahistorical, it must rely on alternative forms of validity for making its knowledge claims. While qualitative methods would reject the notion that there 'is an interpretation which is "correct in itself" ... it is not providing a license for subjectivism, arbitrariness, or irrationality. One is still left with a perfectly good, intersubjectively valid basis for arguing for or against various interpretations. To argue, for instance, that interpretation 2 is more coherent, more comprehensive, and so on, than interpretation 1, is an ample and sufficient reason for deciding to accept it and to take it as "true"' (Madison, 1988: 33).

Elaborating on this concept, Guba and Lincoln (1994) translate the traditional criteria of internal validity, external validity, reliability and objectivity into the corresponding criteria of credibility, transferability, dependability, and confirmability. Kvale (1996) and others consider validity to include communicability, ecological fit, and pragmatic validity. Other scholars have emphasized a variety of alternative criteria for use in adjudicating alternative interpretations and making provisional knowledge claims. These include criteria such as the internal coherence of the interpretation (its harmony with the conceptual whole that it serves), comprehensiveness (its capacity to account for the breadth of available data), contexuality (its ability to retain sensibility within the context from which the work derives), agreement (its articulation with previous knowledge, accounting for, or extending, that which was previously known), and suggestiveness (its 'fertility' in relation to stimulating further inquiry or research). Under these expanded views of regarding the criteria for validity, knowledge claims are understood as socially constituted phenomena; their criteria are derived from and bounded within social and historical contexts. 'The notion that one can "test" interpretations and subject them to scrutiny in the light of the relevant evidence such that objective conclusions can be reached,' observes Madison (1988: 31), 'is a purely utopian notion. This, however, does not mean that interpretation cannot be a rigorous (if not an exact) discipline ... and that one cannot rationally evaluate interpretations.' Qualitative methods satisfy the criteria for knowledge claims through rigorous procedural applications and rational interpretive mechanisms. These methods emphasize the context-bound nature of the conclusions that are drawn, as well as their practical implications for the individuals and cultures involved. Moreover, many qualitative methods impose the additional expectation that the findings must emerge from and be sensibly interpreted within the dialogical relationship between the investigator and his or her participants.

ILLUSTRATIVE METHOD

As an illustration of qualitative assessment in a group therapy context, members might be asked to select and describe their experience of a common, powerful emotion (e.g. depression, anxiety, loneliness). Each member describes his or her experience of the designated emotion in response to open-ended questions from another group member. While one member is serving as the 'teller' and the other is serving as the 'listener', the remaining group members are serving as 'observers'. Members take turns in these roles until everyone has had an opportunity to serve in each role.

The teller's goal is to convey the nature of his or her experience as clearly and fully as possible. The listener's goal is to facilitate the teller's telling in whatever ways(s) she or he can. Open-ended questions, requests for more detail or clarification, or emphasis on particular facets of the feelings may be helpful. Observers' goals include watching for the processes of meaning-making, noting the kinds of interaction that enhance or impede the (co)construction of meaning, and the way(s) in which the experience of emotion is constructed across various tellers.

Neimeyer (2000) describes a number of ways in which data emerge from this kind of interaction, and the value that can be drawn from performing this qualitative assessment. Grounded in their shared roles as listener, teller, and observer, a wide variety of questions can encourage reflection and emotional processing based on this experience. *Role-based* questions (e.g. 'What was the experience of telling/listening/observing like for you, and did it carry or develop any images or feelings?') help deepen the experience and emphasize the co-constructed nature of whatever meanings are ultimately produced or recorded. *Interactive* questions (e.g. 'What was most/least helpful for you as a listener/observer in trying to facilitate the telling?') can highlight the emergent and progressive aspect of meaning-making. And *Emotion-focused questions* (e.g. 'What happened to your feelings as you talked about them; in what ways did they change, move, unfold, or otherwise come to life across the telling?') can highlight idiosyncratic processes associated with emotional expression and transformation.

Common experiences that can emerge from such assessments include:

1. An awareness that the articulation of meaning is an imperfect, effortful and emergent process, both as a teller and a listener.
2. Meaning-making is a developmental process that requires an unfolding across time.
3. Experience is co-constructed. Meaning is made in relation to others; it is an emergent and interactional, rather than stationary and intrapersonal, phenomenon.
4. Describing and experiencing have a dialectical relationship with one another; detailed description of experience can reinvoke aspects of experience, and that experience can yield new possibilities for further description.

Detailed descriptions of a wide range of such qualitative strategies for use in clinical, educational, and developmental contexts can be found in Taylor, Marienau, and Fiddler (2000). All of these strategies share a commitment to the experiential, interpretive, and constructed nature of meaning-making, and for that reason can be understood as falling within phenomenological and constructivist traditions of qualitative assessment.

FUTURE PERSPECTIVES

Among the most prominent developments within qualitative methodologies is the use of computer programs for analysing narrative data. The use of computer programs simplifies the coding, analysis, retrieval, and interpretation of text-based information. As a consequence, these programs help researchers organize and simplify concepts and develop effective models for conceptualizing available data. Overviews of programs for the analysis of qualitative data can be found from the program developer's point of view (Richards & Richards, 1994) and from the user's perspective (Weitzman & Miles, 1995).

Among the most popular programs is NUD*IST (Non-numerical Unstructured Data Indexing Searching Theorizing; Richards & Richards, 1991). Based on the assumptions of grounded theory, it provides a 'tree-structure' of concepts derived from text-based data. An alternative program that creates relational networks from textual data is ATLAS/ti (Muhr, 1991), which provides similar indexing and coding capabilities. While programs such as these facilitate data analysis and interpretation, their use with qualitative data has been questioned in relation to their impact on 'those procedures in the data interpretation which are less or not at all compatible with computer programs' (Flick, 1998: 257).

CONCLUSIONS

The social sciences remain multi-paradigmatic, drawing from the natural, social, and human sciences. The combination of various methodologies in the study of the same phenomenon constitutes a form of 'triangulation', a metaphor borrowed from military strategy where multiple reference points are used to pinpoint an object's exact location. Broadly speaking, convergence between methods enhances our belief that the results are valid and not a methodological artefact.

The joint use of qualitative and quantitative approaches represent a form of methodological triangulation, a common practice in clinical contexts. The triangulation of methods provide an array of data that are useful in their points of divergence, as well as convergence. Convergent data support the nature of the clinical assessment,

whereas points of divergence yield new areas to explore. The combination of various sources of information is consistent with recent shifts within the philosophy of science and re-conceptualizations of the nature of scientific inquiry. In this regard the use of qualitative assessment is designed to diversify, not replace, available forms of quantitative assessment because, as Polkinghorne (1991: 103) has noted, 'only the call for diversity is consistent with contemporary philosophy of science'.

QUALITY OF LIFE

INTRODUCTION

The pursuit of quality of life (QL) is so central to human existence that the question of what is QL and what variables influence QL has been the focus of intellectual debate and scientific investigation from the time of the early philosophers. Current research on QL encompasses many disciplines and issues, including psychology, sociology, medicine, nursing, pharmaceutics, economics, education, architecture, geography, business marketing, the arts, income, employment, and community and environmental concerns.

In 1976, Campbell, Converse, and Rogers published a book that would become a classic, *The Quality of American Life*. Campbell et al. described QL as a vague and ethereal entity, something that many people talk about, but which nobody has a clear idea of what it is. The work by Campbell et al. inspired researchers to search for an accurate definition of QL and to develop QL measurement instruments. A mere glance at the numerous publications recently dedicated to the study of QL would give the reader a fair idea of how highly influential this subject has become at both the basic and applied levels of scientific inquiry. In 1975, the term 'quality of life' was adopted as a 'key word' by the Medical Subject Headings of the US National Library of Medicine to classify research in their computerized search system, MEDLINE. Since then, numerous books and other publications have been exclusively devoted to the study and measurement of QL. Among the many books that have outlined appropriate steps in developing and testing new QL measures, the following stand out: *Quality of Life Assessment. Key Issues in the 1990s*, edited by Stuart R. Walker and Rachel M. Roser in 1993, *The International Assessment of Health-Related Quality of Life. Theory, Translation, Measurement and Analysis*, edited by Sally A. Shumaker and Richard A. Berzon in 1995, *Cross Cultural Health Outcome Assessment: A User Guide*, edited by A. Hutchinson, N. Bentzen, and C. König-Zahn in 1997, and the *Compendium of Quality of Life Instruments*, 5 vols., compiled by Sam Salek and published in 1998. There are now two QL-specialized journals and one electronic catalogue dedicated to investigation of QL issues. *Quality of Life Research* and the *Journal of Happiness Studies* first appeared in 1992 and 2000, respectively. The On-Line Guide to Quality of Life Assessment is a computerized system of programs and databases in the area of health and quality of life assessment that provides guidance on the choice of assessment techniques for specific clinical trials and research projects. This system complements the many large international electronic databases that are so helpful in facilitating the search of QL publications (MEDLINE, CINAHL,

EMBASE, PSYCLIT, PSYCINFO, CLINPSYCH, SOCIOFILE).

THE CONCEPT OF QUALITY OF LIFE

It is important to re-emphasize that QL does not refer to a clearly defined entity with a universally accepted measurement procedure. It is a complex, multifaceted concept which continues to defy consensual definition (Fernández-Ballesteros, 1998). The term QL represents a broad range of domains or dimensions of human existence, ranging from the procurement of basic needs (e.g. food and shelter) and material necessities and goods in general (e.g. means of transportation) to the achievement of a sense of personal fulfilment and happiness. Although there is no consensus on the definition of QL, experts agree that QL is a universal human concept that encompasses both behavioural functioning and subjective psychological well-being. Interestingly, although people from different cultures may differ with regard to the specific basic conditions they have available to them to strive for a good QL, they do not necessarily differ in their reports of how happy and satisfied they are. That is, a person's subjective perception of QL is not a linear reflection of his/her life conditions. This finding does not imply that societal improvements of life conditions are irrelevant to the betterment of QL but draws attention to the fact that human perception may be the most important common denominator in QL research.

Authors have proposed definitions of QL in terms of satisfaction with different life domains, ranging from the material and financial to the political and other aspects of well-being (see Table 1). To date, the domain that has drawn the most investigation and interest is the subject of 'health'. The two main objectives of health care are to increase longevity and to improve QL in the years before death, with QL defined as level of behavioural functioning or the ability to 'do stuff' (Kaplan, 1994). Thus, it might be important to distinguish between QL in general and *health-related* QL (HrQL) in particular (Kaplan & Bush, 1982; Jenkins, 1992). In contrast with the global term QL, HrQL is more descriptive, focuses on dimensions of health status, and directly links QL

Table 1. Selected definitions of quality of life and health-related quality of life

Quality of Life
The subjective perception of satisfaction or happiness with life in domains of importance to the individual (Oleson, 1990).
The multidimensional evaluation, by both intrapersonal and socionormative criteria, of the person–environment system of an individual in time past, current and anticipated (Lawton, 1991).
A concept encompassing a broad range of physical and psychological characteristics and limitations which describe an individual's ability to function and to derive satisfaction from doing so (Walker & Rosser, 1993).
The ability of the self to build and manage a balance between the body, mind and spirit in searching for a state of well-being and to establish and maintain an harmonious relationship with the environment (Albrecht & Devlieger, 1999).
Individuals' perceptions of their position in life in the context of the culture and value systems in which they live, and in relation to their goals, expectations, standards and concerns (WHOQOL Group, 1995).
The degree to which a person enjoys the important possibilities of his or her life in three main areas (being, belonging, becoming) (Raphael et al., 1999).
What a person does and how the person experiences what he/she does and be (Reig et al., 2001).
Health-related Quality of Life
The value assigned to duration of life as modified by impairments, functional states, perceptions, and social opportunities that are influenced by disease, injury, treatment, or policy (Patrick & Erickson, 1993).
The functional effect of an illness and its consequent therapy upon a patient, as perceived by the patient. Four broad domains contribute to the overall effect: physical and occupational function; psychological state; social interaction; and somatic sensation (Schipper et al., 1990).
Includes three Fs: feelings, functions, and futures; at least five levels at which human life is lived, including biological, psychological, interpersonal-social and economic; and quality of life data should be based as much as possible on observable or specific descriptive phenomena (Jenkins, 1992).
The subjective perception of the impact of health status, including disease and treatment, on physical, psychological, and social functioning and well-being (Leidy et al., 1999).

to the concept of disease or illness (see also Bullinger, 1997). For example, studies have shown that chronically ill patients are interested in their medical-test results (e.g. blood counts) to the extent that the tests predict future survival and behavioural functioning.

Thus a two-dimensional framework that includes behavioural doing (rewarding activities) and subjective well-being may provide the best measure of QL. Health and money can be seen as individual resources that may contribute but are not sufficient to living a life characterized by plenitude and happiness. Like Mihaly Csikszentmihalyi (1997) tries to convince us, the quality of our lives will be much improved simply by learning to love what we do and what we have to do. Other behavioural researchers even avoid talking about 'quality of life' as a single construct. These authors prefer to distinguish between specific *life qualities* that should not be lumped and added up into a single QL measure. For example, Ruut Veenhoven's model focuses on four separate qualities of life: (1) livability of the environment; (2) life-ability of the person; (3) utility of life for the environment; and (4) appreciation of life by the person (Veenhoven, 2000).

Table 2. Some of the quality of life instruments

Sickness Impact Profile (Bergner et al., 1976): measures the impact of illness on the patient's functional behaviour.

Quality of Well-Being Scale (Kaplan et al., 1976): measures performance and preference with regard to limitations in physical, self-care and social activities.

General Health Rating Index (Ware et al., 1978): deals with the patient's perception of health and the impact that disease has on physical activities.

Nottingham Health Profile (Hunt & McEwan, 1980; Hunt et al., 1986): evaluates the symptomatic evidence of sickness and its impact on daily activity.

Sptizer Quality of Life Index (Spitzer et al., 1981): aims to identify the components of quality of life and is primarily intended for monitoring cancer patients before and after therapy.

McMaster Health Index Questionnaire (Chambers et al., 1982): concerned with physical, social and emotional aspects of life without relating them to the symptoms of the patient.

The COOP Function Charts (Dartmouth COOP Functional Health Assessment Charts/WONCA) (Nelson, Landgraf, Hays et al., 1990): measures patient functional status through an overall assessment of biological, physical, emotional and social well-being, and quality of life in order to facilitate communication between patients and clinicians.

The European Quality of Life Scale (EQ-5D) (The EuroQol Group, 1990, 1993): consists of a questionnaire which classifies the individual into one of 243 health states (5 dimensions, each with 3 levels) and a visual analogue scale on which individuals rate their own health between 0 and 100. Provides a simple descriptive profile and an overall numeric estimate of QL which can be used for both clinical and economic evaluations of health care.

Medical Outcome Study 36 Item Short Form Health Survey (Ware & Sherbourne, 1992): designed to survey health status in clinical practice and research by evaluating health-related dysfunctions in eight areas of daily activity.

WHOQOL-100 (WHOQOL-BREF) (The WHOQOL Group, 1994, 1995): a measure of 24 facets relating to QL for use in a diverse range of cultures.

Quality of Life Questionnaire (Ruiz & Baca, 1993): measures the basic issues (social support, general satisfaction, physical/psychological well-being, absence of work overload/free time) that a healthy adult population considered important when quality of life was being evaluated.

Schedule for the Evaluation of Individual Quality of Life (SEIQoL) (McGee et al., 1991; Browne et al., 1994): allows individuals to nominate, weigh, and assess those domains of greatest relevance to their quality of life.

Questions on Life Satisfaction (FLZm) [Fragen zur lebenszufriedenheit Module] (Henrich & Herschbach, 2000): a standardized, economical questionnaire consisting of two modules (general life satisfaction and satisfaction with health) conceived of as measures of general quality of life and health-related quality of life, respectively.

Perceived Quality of Life Item [In general, would you say your *quality of life* is: very good; good; fair; poor; very poor] (Reig et al., 2001): a single-item self-report instrument which uses a single question to measure the concept of interest.

For sources see: Fernández-Ballesteros (1998) and Salek (1998).

THE ASSESSMENT OF QUALITY OF LIFE

The selection of an appropriate tool to measure QL is the most important task in the assessment of QL simply because measurements can only be as reliable and valid as the instruments used to obtain them. Table 2 lists some of the many available QL measures that have been useful in advancing our understanding of QL.

Research results obtained with the instruments listed in Table 2 indicate that outcome evaluations of most healthcare interventions are not valid without the patient's subjective evaluation of the outcome. These results also concur in that QL is a dynamic construct where by a person's attitude toward a particular aspect of QL may change over time through such psychological phenomena as adaptation, coping, or expectation.

This body of research has also contributed to identification of variables that are associated with poor QL (e.g. old age, being female, low educational attainment, living without a partner, and disorder comorbidity). However, researchers have also noted that although physical functioning declines with advancing age and with the development of chronic disease, mental health remains remarkably stable and independent of chronic disease and advancing age. Moreover, perceptions of personal health, well-being, and life satisfaction are often uncorrelated or discordant with medical health status and degree of disability. This phenomenon has been called the 'disability paradox' (Albrecht & Devlieger, 1999).

The disability paradox can be defined in two ways. On the one hand, it seems impossible that people with disabilities can report having a good or excellent QL and at the same time indicate they encounter serious limitations in their performance of daily activities and of social roles, as well as being the target of persistent discrimination. It is also contradictory that while over 50% of individuals with disabilities report enjoying a good or excellent QL, laymen, physicians and healthcare professionals continue to perceive individuals with disabilities as having a poor QL. From either perspective, the point is that instruments that equate QL with health and physical normalcy ignore that individuals can adapt and cope with health and physical restrictions.

If QL measures show that many of those living with health problems are in fact in far-better shape than objective measures would predict, the assumptions underlying the evaluation of health-related outcomes must be reconsidered. Albrecht and Devlieger (1999) posit that the relationship between objective medical health and subjective perceptions of QL results from a balancing act between a person's body (organic and physical function dimensions), mind (rational and intellectual capacities of the self) and spirit (recognition that the self is part of a higher being or that having a purpose in life larger than and extending beyond the self). These authors argue that whereas illnesses and dissatisfaction with life reflect distortions of the body–mind–spirit balance, good QL in the presence of adversity reflects a reconstituted balance. As a holistic concept, quality of life goes beyond disease categories and daily activities and directs attention to the more complete social, psychological and spiritual being. From this perspective, one-dimensional instruments are ill designed to capture the complex processes that interrelate social contexts, emotional adaptation and dynamic subjective perspectives into shaping the QL of individuals.

Various methodological issues and a number of technical and practical considerations need to be considered in selecting QL and HrQL instruments. Methodologically, psychometric considerations, such as reliability, validity, discriminatory power, and responsiveness to change, are important. Technical considerations include choosing among the many types of QL measures, which are generally classified as global, individual, generic, specific (for therapeutic/function, condition, situation, population), battery, and utility or preference instruments. For example, generic instruments are designed to measure QL over a wide range of populations, medical conditions, and personal functioning. On the other hand, specific instruments are a better choice when the investigator wants to focus on the problems associated with specific diseases, disabilities or patient groups. Yet another preferred solution could be taking a modular approach, where a generic and widely applicable core of items would be supplemented by more specialized scales. Technical aspects also include a wide variety of other choice decisions ranging from response formats (e.g. true/false vs. multiple choice), scaling (e.g. 1–10 vs. 0–3) and weighting techniques, instrument length (e.g.

single-item vs. multiple items), and report presentation (e.g. indices vs. profiles) to the degree to which the instrument will be sensitive across languages and dialects, customs, beliefs and cultures.

Practical considerations go beyond the question of whether or not the data will be useful or applicable to real-life situations. Practical considerations may guide decisions that include selecting (a) when, where and how long it takes to administer the instrument, (b) the administration method (direct observation, face-to-face interview, telephone interview, self-administered questionnaires, proxy respondents), (c) strategies that increase responding ratios, (d) methods of data processing and analysis that minimize error, (e) methods associated with low administration costs, (f) ways of reducing discomfort to the participants, (g) how to train personnel to standardize the data collection process, (h) methods for data diffusion and presentation, and (i) ways to assure that ethical considerations are respected (e.g. confidentiality). These decisions are very important and can dramatically influence experimental findings. For example, in studies investigating the QL of clients or patients, informal or formal caregivers can provide proxy evaluations that add or complement the patients' self-report evaluations. In comparison with patients' self-reports, these studies often find that proxy respondents tend to report lower functioning and lower quality of life of the patients.

FUTURE PERSPECTIVES

Despite considerable methodological and analytical advances over the past two decades, further work is required. Recent studies during the 1990s have benefited from and contributed to: (a) the increase knowledge of effective formatting methods that benefit data quality (Mullin et al., 2000); (b) the development of shorter measures (e.g. COOP/WONCA charts; SIP-30; SF-24; NHP-12) that decrease the burden on patients; (c) more sophisticated analytic techniques and better approaches to interpreting results; (d) new theoretical models; (e) the development of individualized measures; (f) the emergence of computerized testing; (g) the inclusion of QL information to administration bases; and (h) more careful consideration of ethical concerns (Wood-Dauphinee, 1999).

There are many theoretical models that attempt to explain and identify the determinants of QL using both objective and subjective QL indicators. The names of these theories are: Standard Needs Approach, Bottom-Up Influences, Relative Standards, Social Production Function Theory, Psychological Processes Approach, Culture, Personality and Genetic Predisposition Theories, Discrepancy Theories, Goals Theory, Adaptation and Coping Theory, and the Evaluation Theory (see Browne, McGee & O'Boyle, 1997; Diener & Lucas, 2000). Although each of the theories is supported by evidence, none of the models by itself explains all of the data.

Important advancements to cross-cultural instrument development come from several research groups. *The European Group for Quality of Life and Health Measurement Group* uses the *Nottingham Health Profile*. The *European Organisation for Research and Treatment of Cancer* initiated the development of the *EORTC Quality of Life Questionnaire* in 1986. *The International Quality of Life Assessment Project Group* was formed in 1991 and developed the *SF-36 Health Survey*. *The European Quality of Life Project Group* contributed to the development of the *EUROQOL Questionnaire*. Finally, the *World Health Organization Quality of Life (WHOQOL) Group* was formed with the aim of developing a quality of life instrument by simultaneous study in different cultures.

CONCLUSIONS

QL and HrQL measures are used for the purpose of (a) understanding the determinants, causes and impact of QL within individuals and across groups, (b) assessing and monitoring the impact of social and environmental conditions on QL, (c) evaluating the outcome of the effects of health and social policies, and of clinical interventions, and (d) helping policy-makers (e.g. allocating resources in relation to need). QL information can also be useful for promotional purposes to industry and formulary listings of providers. Clearly, such wide range of purposes is not likely to be satisfied by any single questionnaire or indicator. An instrument designed for one purpose (discriminative, predictive, or evaluative) will not necessarily work well when used for

another purpose because the properties required in any given instrument depend on the specific purpose for which the instrument will be used (Leidy et al., 1999; Wu & Cagney, 1996).

There is a considerable variation in the quality and sophistication of the available QL measures. This variability may be the result of the relative newness of the field, where the development of QL instruments is a recent endeavour compared with measurement advances in the fields of personality, intelligence, or public opinion. Nonetheless, assessment of the patient's experience of disease and treatment is now acknowledged as a central component of healthcare and healthcare research. Research findings in the area of QL have great potential for contributing to alleviate suffering, minimize discomfort and morbidity, and improve medical health and subjective well-being. Thus, continuous efforts to improve upon current QL assessment efforts should prove to be a worthy human endeavour.

RELIABILITY

INTRODUCTION

Reliability as a central concept of test theory dates back to the beginning of the 20th century. It is based on the existence of intra-individual variability as well as variation between persons. With intra-individual variability or measurement error, true score was also introduced as a central concept of classical test theory. Observed score variance could then be thought of as true score variance plus error variance. The reliability of a test, rating scale, assessment or any other more or less standardized procedure within a given (sub)population of persons (or other objects of measurements, e.g. classrooms) is defined as the ratio of true score variance to observed score variance or as the squared correlation between observed scores and true scores (Lord & Novick, 1968: 61):

$$\rho_{XT}^2 = \frac{\sigma_T^2}{\sigma_X^2} = \frac{\sigma_T^2}{\sigma_T^2 + \sigma_E^2} (= \rho_{XX'})$$

Its minimum value is zero, its maximum value one. As will be demonstrated, the definition is not very useful until we have defined precisely what we mean by 'error'.

After the 1960s, Item Response Theory, IRT for short, became an influential approach in test theory. With IRT person parameters on a latent scale replace true scores. At first sight, there seems to be no place for reliability within the context of IRT. It can be demonstrated, however, that reliability is an important concept in the newer test theoretical approach also.

RELIABILITY AND SOURCES OF VARIATION

When the length of a person is measured repeatedly, we notice small differences in the reading of the length: there is error in the measurements. The same is the case in measuring a person's characteristics in psychological testing. When an intelligence test would be administered to a person repeatedly, we would expect scores to vary: again there is measurement error. Unfortunately, the experiment of repeatedly testing a person with the same measurement instrument is seldom done; in practice we should expect memory effects. Instead, we could administer two tests meant to measure the same construct. Then a score difference might not only be due to chance fluctuations in item responses, but also to differences in content. Many more sources of variation can be thought of; for example, systematic fluctuation of responses over time. Sources of variance due to person characteristics can be classified as lasting or temporary, and lasting or specific. Further, there are factors affecting test administration and there is a category for variance not accounted for

otherwise. Most of the sources of variation in responses might be regarded as a source of error variation, but the same sources might be regarded as sources of true variation, depending on the purpose of the test administrator. Let us give an example, mentioned by Stanley (1971: 366), who discusses the subject of sources of variation extensively. A person may be fatigued on the day of testing and this influences test performance. When our interest is to predict performances over some period, reliability would be consistency over time. When the intercorrelations among tests administered at the same session are studied, consistency at that session is relevant. So, the definition of error depends on the purpose of the investigator, and this should determine the choice of reliability coefficient(s).

RELIABILITY COEFFICIENTS: PARALLEL-TEST, TEST–RETEST METHOD AND SINGLE-ADMINISTRATION

A parallel test is defined as a test on which true scores and error variances are identical to those of the first test: two parallel tests are exchangeable. If we administer two parallel tests in one test session, we can easily obtain a parallel-forms reliability or equivalence coefficient. The reliability of either of the two tests equals the correlation between both tests. There are several disadvantages, however. First, theoretically there is no unique set of parallel tests. This advantage can be circumvented by precisely describing the characteristics which makes tests parallel. Second, parallelism of tests can only be verified when we have at least three tests. Alternative models that may be used for the estimation of reliability are: tau-equivalent tests, essential tau-equivalent tests and congeneric tests. In tau-equivalent tests true scores are identical, but error variances are unequal, in essential tau-equivalent tests true scores are identical apart from an additive constant, and in congeneric tests true scores on different test forms are linearly related. A reliability estimate based on the assumption of congeneric test forms can be obtained for three or more tests. The hypothesis that tests conform to the congeneric test model can, however, only be tested when at least four different tests are administered. Finally, the extra time needed for administering another test might be difficult to get or might instead be used for lengthening the original test, making this test more reliable.

A special case of alternate forms arises when behaviour is rated by two or more raters. The interrater correlation seems to be the obvious choice as a reliability coefficient, but it neglects differences in e.g. rater severity. An alternative approach is to use generalizability theory. When raters have only a few observational categories at their disposal, frequently a nominal measure of agreement (see Cohen, 1960) is used instead of a reliability coefficient.

Another method to obtain test reliability is to administer the same test again on a second occasion. When the interval between the two occasions is small, there is a large risk that persons remember their responses at the first occasion. With a larger time interval the risk that persons have changed is large. So, the test–retest method is useful only when the characteristic being measured is a stable characteristic. The resulting reliability coefficient is therefore called a stability coefficient. When a stability coefficient is used, it is important for the test developer to report the time interval of the reliability study as information on details is always important (Standards of Educational Testing, APA, AERA & NCME, 1999: 32).

There is a third method for the estimation of reliability, based on a single administration of a test. This approach is viable when a test is not speeded and consists of several parts or items. The various estimates suggested with this approach are discussed in the next section.

Table 1 gives an overview of the major approaches to reliability estimation and the corresponding reliability coefficients.

RELIABILITY COEFFICIENTS BASED ON A SINGLE ADMINISTRATION OF A TEST

Assume that a test can be divided into two parallel part-tests; this might be done by pairing similar items and allocating the two items to different part-tests. Then the reliability of both half tests is obtained as the correlation between the two part-tests. The reliability of the total test

Table 1. Major approaches to reliability estimation

Reliability coefficient	Major error source	Data-gathering procedure	Statistical data-analysis
(1) Stability coefficient (test–retest)	Changes over time	Test–retest	Product-moment correlation
(2) Equivalence coefficient	Item sampling from test form to test form	Give form j and form k	Product-moment correlation
(3) Internal consistency coefficient	Item sampling; test heterogeneity	A single administration	(a) Split-half correlation & Spearman–Brown correction coefficient alpha (b) λ_2 (c) Other

can be obtained using the Spearman–Brown formula for a lengthened test

$$\rho_{X(k)X'(k)} = \frac{k\rho_{XX'}}{1 + (k-1)\rho_{XX'}}$$

where k is the factor with which the test must be lengthened (in this case $k = 2$). Several other coefficients have been suggested based upon a split of a test into two or more parts. An overview of coefficients is given by Feldt and Brennan (1989). We mention a few coefficients.

When a test has more than two parts, a split into two parts is arbitrary. Several coefficients have been proposed in which all items or units or testlets play a symmetrical role. The units might include several items thought to have correlated errors; this might be the case when, for example, a number of items is related to a particular text.

The most popular coefficient is coefficient alpha,

$$\alpha = \left(\frac{n}{n-1}\right)\left(1 - \frac{\sum \sigma_i^2}{\sigma_X^2}\right)$$

which can be simplified to KR20 for dichotomous items. It is a lower bound to reliability. In many situations, however, the coefficient gives a reasonably accurate estimate of test reliability; it is equal to reliability if items are essentially tau-equivalent. Researchers have sought for better lower bounds; they even have sought for the 'greatest lower bound' to reliability (Ten Berge, Snijders & Zeegers, 1981). A better lower bound to reliability than coefficient alpha is Guttman's λ_2. Presently, coefficient alpha is available in statistical software packages. It can also easily be computed with a spreadsheet. Guttman's λ_2 is also available in present-day software.

Another approach to test reliability is to split the test into several parts thought to be congeneric. Estimated model parameters of the congeneric test model can be used for the computation of the reliability of the total test. With three part-tests the computation is easy, but the model assumptions cannot be verified. With more than three part-tests a program for structural equation or SEM modelling like EQS or LISREL must be used (Jöreskog, 1971). More in general, fitting SEM models results in estimates of psychometric characteristics of the tests involved in the model.

With random sampling of dichotomously scored items, where each examinee responds to a different sample of items, another reliability coefficient is relevant: KR21, in the past known as an approximation to KR20.

The value of the reliability coefficient is subject to sampling fluctuations. References to the literature on sampling fluctuations, especially theory relevant to the comparison of reliability coefficients, can be found in Feldt and Brennan (1989: 126–127). The bootstrap method can also be used for the construction of a confidence interval. Raykov (1998) presented a bootstrap study with respect to reliability.

THE RELIABILITY OF TEST BATTERIES AND STRATIFIED TESTS

Many tests have strata or subdivisions covering various aspects of interest. The subtests may or may not be of interest on their own; an example of the latter case is a verbal subtest in a test battery. Either way, let us assume that the reliabilities of the subtests have been estimated. Then the reliability of the total test is easily

computed with the formula for the reliability of a composite test

$$\rho_{XX'} = \frac{\sum \rho_{ii'}\sigma_i^2 + \sum\sum \sigma_{ij}}{\sigma_X^2}$$

When the reliabilities of the subtests are estimated with coefficient alpha, the reliability coefficient for the total test is the stratified-coefficient alpha.

MAKING A TEST MORE RELIABLE

It is possible that in a preliminary investigation the test is deemed too unreliable for accurate measurement. Several measures can be taken, in isolation or in combination, to improve the reliability of the test scores:

- Add items. The Spearman–Brown formula for the reliability of a lengthened test can be used for the estimation of the number of items needed to obtain the desired test reliability. Its use presupposes the addition of items similar to those already in the test.
- Eliminate items. Reliability can be improved by eliminating an item with a low/negative item–rest correlation, the correlation between item and the remaining test items.
- Use optimal item weights. There are several definitions of what optimal weights are. 'Maxalpha' weights maximize coefficient alpha (not reliability itself), 'maxrho' weights maximize the reliability of a set of congeneric measurements (Jöreskog, 1971). Maxalpha weights, including the differential weighting of response alternatives, is achieved in a homogeneity analysis or dual scaling (Nishisato, 1994). In IRT models items have optimal weights other than unit weights, with the exception of the Rasch model. There are two problems with item/option weighting: first, the empirical weights are liable to sampling fluctuation; second, the scoring rule should be acceptable to test takers.
- Improve instructions in order to better standardize test administration. Unreliability can be brought about by less than ideal testing circumstances or scoring procedures. When scoring is done by raters, reliability might be improved by more stringent scoring instructions.

RELIABILITY AND VALIDITY

In the end a test must be valid. A test can have different validities, depending on the various uses of a test. The maximum validity of a test is bounded by its reliability: the validity can never exceed the square root of the reliability; in other words, it can never exceed the correlation between the observed scores and the true scores on the test. The correction of attenuation

$$\rho_{T_X T_Y} = \frac{\rho_{XY}}{\sqrt{\rho_{XX'}\rho_{YY'}}}$$

gives the correlation between true scores of two variables.

RELIABILITY AND THE STANDARD ERROR OF MEASUREMENT

From the variance of observed scores and the reliability, the true-score variance and the variance of measurement errors can be computed.

The standard error of measurement, the square root of the variance of measurement errors, can be used for the construction of a confidence interval of a person's true score. This application can be criticized for two reasons. This will be explained later in this section and in the next section.

The standard error of measurement depends not only on the test accuracy, but also on the scale that is chosen. When, for example, length in centimetres is converted to length in inches, the standard error for the measurement of length changes. Reliability, on the other hand, is dimensionless, but depends on the variation of the true scores in the population.

Neither the reliability coefficient nor the standard error of measurement is sufficient to adequately describe the accuracy of a test. For, the variance of errors of measurement should be conceived as an average value, averaged over true score levels. The test developer should also obtain and report information on the conditional error variance (APA, AERA & NCME, 1999: 27). These might be obtained from an IRT-analysis or

from other approaches. A recent discussion of some methods to obtain conditional error variances is given in Lee, Brennan, and Kolen (2000). The possible dependency on the true score level is one reason to be careful with the use of the standard error of measurement for the construction of a confidence interval.

RELIABILITY AND THE ESTIMATION OF TRUE SCORES

The observed score of a person is not the only estimate of his/her true score. The best linear prediction formula is Kelley's formula

$$\hat{\tau} = \rho_{XX'}x + (1 - \rho_{XX'})\mu_X,$$

in which the overall mean of the test scores plays a role, besides the observed score. The lower the reliability, the more the true-score estimate regresses to the overall mean. The Kelley-estimate is not without problems either. One might, for example, obtain a different Kelley-estimate for persons from different populations, which may lead to questions about allocation of persons to populations, for example 'male' and 'female', and the fairness of possible decisions based on its use.

The estimation of true scores by means of a regression formula can be generalized to the estimation of true scores on more than one test. Then the best estimate of a person's true score is based on the scores obtained for several tests. The importance of a test in such a 'prediction' formula depends on its reliability, among other things.

RELIABILITY AND EQUATING

Sometimes it is necessary to develop multiple forms of a test, because the content of a test becomes known to potential test takers after some time. In order to be exchangeable the test forms should be parallel. In case they are not parallel, they should be equated. If tests have different reliabilities, they cannot be equated. In that case one has to resort to, for example, linear true score equating (Kolen & Brennan, 1995). Reliabilities of the tests to be equated and the anchor test used for equating are needed in order to obtain estimates of the standard deviations of true scores, although under some assumptions the explicit computation of reliabilities can be avoided (Angoff, 1971: 582–583).

RELIABILITY AND THE VARIATION IN TRUE SCORES

From the definition it is clear that for a fixed test reliability depends on the variation of true scores. The reliability of a test can be high in one population and low in a second population. In some applications, low test reliability is not an issue since differentiation between persons is not a goal of the testing application. This happens, for example, in criterion-referenced measurement, where examinees are not compared with each other, but with a standard of performance. For this situation, alternatives to the traditional reliability coefficient have been proposed. One of these proposals has been to use a coefficient of decision consistency instead (see, for example, Huynh, 1978). Decision consistency is not, however, a topic that belongs to the subject of reliability proper, defined as a psychometric concept.

RELIABILITY AND IRT

Variation between persons remains important in IRT for several reasons. Without variation there is no use for modelling that includes a latent trait and there is no data that can guide our choice between models. With only a little variation accurate estimation of item parameters (in terms of standard errors of parameter estimates) is not possible for most IRT models. Above all, when there is no variation, shouldn't the conclusion be that the trait is unimportant for differentiating between persons? Actually, many estimation programs compute IRT model parameters with a distribution of latent person parameters or abilities, the IRT-counterparts of true scores, that has a standard deviation equal to one. The size of the test information and its reverse – the error variance associated with the estimation of a person parameter – can then easily be interpreted with a reference to the variation of abilities. Actually, one can set up the computation of the reliability of measurements on a given latent scale given (an approximation to) the ability

distribution and the conditional error variances that can be obtained from the test information. In computerized adaptive testing, or CAT, it is possible to maintain the same level of accuracy over the relevant range of abilities. The problem that the error variance in the definition of reliability is only an average value becomes a lesser problem in this way. Bock and Mislevy (1982) in their work on CAT explicitly derive the reliability of the suggested CAT-procedure.

GENERALIZABILITY THEORY, OBJECTIVITY, VALIDITY (GENERAL)

REPORT (GENERAL)

INTRODUCTION

The psychological report presents an opportunity for the professional psychologist to present the results of assessment in a case-focused, problem-solving manner. Its major purpose is to help the referral source make decisions related to the client. It thus represents the end product of assessment. An ideal report will be written according to general guidelines and in a flexible but predictable format.

The most frequent categories of reports are centred around questions related to intelligence/achievement, personality/psychopathology, and neuropsychology areas (Camara et al., 2000). Additional, less frequent categories include adaptive/functional, developmental, neurobehavioural, aphasia, and behavioural medicine/rehabilitation. The most frequent general issues relate to diagnosis and answering which type of treatment would be most effective for a given client. Each of the various categories of assessment require different types of

assessment instruments, knowledge related to the type of difficulty, awareness of the context (educational, legal, medical, rehabilitation, forensic), and knowledge of the various resources available in the community. This knowledge will then be integrated into the report in order to make it more problem focused and relevant to the referral source.

GENERAL GUIDELINES

The *length of the report* varies considerably across various referral settings. Traditionally, psychological reports have been between four and seven single-spaced pages. In medical contexts where time efficiency is crucial, psychological reports rarely exceed two pages. However, psychological reports in a wider number of contexts also appear to be getting shorter due to the cost containment and time efficiency demands of managed healthcare. In contrast, legal contexts demand far more detail, require greater accountability, typically have more complex referral questions, and involve more flexible, ample methods of reimbursement. As a result, reports tend to be 7–10 pages and sometimes even longer. Reports are therefore influenced by and formatted according to the conventions of other health professionals working within the contexts psychologists write for.

A well written report also pays particular attention to the *degree of emphasis* given to the various points. Sometimes, the evidence for a conclusion will be consistent, strong, and clear and this can then be stated accordingly in the report. Other information might be more speculative and should be written with an appropriate degree of tentativeness.

Test interpretations are ideally presented and organized around specific *domains*. The selection of which domains to include should be driven by the types of questions the referral source is requesting. These questions largely determine the types of assessment tools used and types of questions asked of the resulting data. Since each client is different and lives within a different context, the number of domains will vary considerably. Within a psychoeducational context, relevant domains might revolve around cognitive ability, level of achievement, presence of a learning disability, or learning style. In contrast, a report written to assess personality/psychopathology might focus more on such areas as coping style, level of emotional functioning, suicide potential, characteristics relevant to psychotherapeutic intervention, or diagnosis.

Sometimes test results are presented in a test by test fashion. This has the advantage of making it clear where the data came from. However, it runs the risk of being overly data/test oriented rather than person oriented. Research has consistently indicated that readers of reports do not feel this style is 'user friendly' (Tallent, 1993). In addition, it indicates a failure to integrate data from a wide number of sources and suggests that the practitioner has not adequately conceptualized the case. It also encourages a technician-oriented role rather than one in which a knowledgeable clinician integrates a wide array of information to help solve a client's problem.

Consistent with the above themes, *deciding what to include* is largely determined by the referral source. One general principle is that material should only be included if it helps to further understand the client. In this respect, what is unique rather than what is average is usually more important. For example, describing a client's appearance is typically not useful if they made modal responses to the test material and were dressed in average appropriate clothes. In contrast, a client who was obsessively concerned with accuracy (ignoring time concerns) and dressed in an unusually formal fashion does provide useful behavioural observations. These observations also help to place test scores in a wider context, give information related to coping style, and an indication of their personality type.

Generally *raw data and quantitative scores* should be avoided in the impressions/interpretations section of the report. They can potentially make the report seem overly technical and cluttered. Sometimes, however, providing concrete behavioural observations or actual responses to selected items (i.e. MMPI-2 critical items) can make abstract points seem more immediate and insightful into the content of the person's thought processes. This can serve to balance out more high level abstractions. In addition, providing a clear statistic such as a percentile can sometimes make a description seem more clear and accessible. For example, a report might describe how a client with an average IQ had a quite low auditory memory. Stating they

only scored in the '5th percentile' (or 'only five people out of a hundred scored in this range') can provide some precision into the magnitude of their difficulties.

One of the crucial roles of a psychological report is to assist in providing *client feedback*. This is in accordance with client advocacy legislation and the American Psychological Association's ethical guidelines in that clients should know the types of information and recommendations being made about and for them. Such feedback is expected to be clear, accurate, direct, and understandable. This means the results need to be phrased in everyday language rather than formal psychological terminology. There has also been increasing evidence that well integrated client feedback has clear therapeutic benefits (Friedman et al., 2000; Gass & Brown, 1992). Thus the report (and related feedback) can potentially become an integral part of therapy itself. While feedback is typically verbal, an important option is to design the written report, or at least an edited version of the report, in such a way as to be of optimal benefit to the client.

FORMAT FOR PSYCHOLOGICAL REPORTS

There are various ways of organizing a psychological report. Some practitioners prefer to use an informal, relatively unstructured letter format. This is especially appropriate when the report will be seen by a single referral source and the referring person is known to the practitioner. Other reports might be more appropriately organized around quite structured headings (i.e. 'Referral question', 'Test results', 'Summary and recommendations'). Some reports might demand (and practitioners prefer to include) an extensive history whereas others might minimize the history in favour of spending relatively greater time elaborating on impressions and interpretations. Given the recent trends towards treatment planning and demonstrating the practical, everyday relevance of assessment (i.e. Beutler & Williams, 1998; Maruish, 2000; Sbordone & Long, 1996), some reports might place relatively greater emphasis and length into providing concrete, specific recommendations for psychotherapy planning, vocational training, educational intervention, or neuropsychological rehabilitation.

Even if reports do not formally designate specific headings and subheadings, they still typically include a predictable series of content areas. The following listing provides an outline of typical areas (from Groth-Marnat, 1999; Williams & Boll, 2000):

Name:
Age (date of birth):
Sex:
Ethnicity:
Date of report:
Name of examiner:
Referred by:

I. Referral question
II. Evaluation procedures
III. Behavioural observations
IV. Background information
V. Test results
VI. Impressions and interpretations
VII. Summary and recommendations

An additional feature is an indication at the top of the report that the report is 'Confidential'. The report should conclude with the signature, name, and title of the author. This is crucial since it indicates that responsibility for the contents of the report is being formally accepted by the author. Identifying information is fairly straightforward (name, age, sex, etc.) but the additional features (I–VII) require elaboration.

The *referral question* sets the stage for the rest of the report. It is therefore especially important to make sure it is as clear and specific as possible (i.e. 'My understanding is that you would like me to evaluate Mr. X with particular reference to the nature and severity of his deficits, the extent of care he would require, ability to work, personality functioning, and the likelihood of any further improvement'). Often clarifying the referral question will require discussions with the referral source since it is not unusual to have an initially poorly articulated (or at least partially developed) referral question. One means of assisting with this is to ask the referral source what decisions they need to make related to the client. Sometimes discussions with the referral source will mean indicating the sorts of questions that can and cannot realistically be answered through formal assessment. Such discussions may

even result in a mutual decision that formal assessment is not appropriate for the case. A clearly articulated referral question will carry through to the rest of the report in that it provides a frame of reference for this material as well as a rationale for what is relevant to include in the sections on background information (history), impressions/interpretation, and especially the summary/recommendations section. One effective technique is to create bulleted points in the summary, each of which provide a clear answer to each of the referral questions. However, the points need to be consistent with material presented previously in the impressions/interpretation section. A nice beginning to the referral question section (and the report in general) is to make a brief, succinct, orienting, statement related to the client (i.e. 'Mr. X is a 36 year old, white, right handed, married male with a high school education who sustained a severe, diffuse closed head injury on April 12, 1998').

The *evaluation procedures* section is simply a listing of the various instruments used. Sometimes, particularly in legal settings, this includes the date when administered and the length of time they took to complete the test. It is sometimes useful to include the total time involved in the entire evaluation. If the report relied on previous records (academic, vocational, legal, medical), then the dates and, if relevant, the authors of the reports should be given (i.e. 'In addition, I reviewed the following reports by ...').

Often *behavioural observations* can provide a useful context for understanding test data. For example, low scores on cognitive tests may be the result of low motivation or perhaps a problem solving style that sacrifices speed for accuracy. These and related behavioural observations can be noted in the behavioural observations section. Behavioural observations should generally be kept concise and relevant. They should also refer to concrete, observable behaviours rather than either high level abstractions or conclusions about the client. Thus, it would be preferable to state that the client moved slowly and they were self-critical (i.e. 'the client continually commented that they weren't able to do very well') rather than to make inferences (i.e. 'the client appeared depressed'). Inconsistencies in the client's behaviour might also be useful to note. These might include a young person who acts older than their stated age or a person who says they feel fine but appear anxious and defensive. Additional domains of behavioural observations include attitude toward the examiner and test situation, attitudes toward self, reaction to praise, reaction to failure, motor coordination, reaction time, and behaviours related to speech and language.

One of the potentially most useful functions of the professional psychologist is to provide descriptions of relevant *background information*. This might be particularly important in a medical context where physicians neither have the time nor the appropriate training to access important client information. At the same time, the background information section should avoid being overly inclusive. For example, it is unlikely to be useful to provide a detailed developmental history for an adult who is seeking vocational assessment. On the other hand, a detailed developmental history would be essential for an adolescent referred to assess possible learning disabilities. It is usually important to clarify where the information came from (i.e. 'The client reported that ...' or 'The report of 3/6/98 by Dr. Y indicated that ...'). Possible domains for history taking and inclusion in the background information section include the following: history of the problem, medical history, vocational/employment background, family background, personal history (infancy, early/middle childhood, adolescence, early/middle adulthood, late adulthood), and miscellaneous areas such as fears, self-concept, recurring dreams, or specific memories.

Some reports include a *test results* section which lists the actual scores on the tests. If this is done, it is often useful to translate the scores into percentiles to enable readers to more easily understand the meanings of the test scores. A further related strategy is to develop a profile sheet depicting relative high and low performances. Sometimes these might have cutoffs for such categories as 'impaired', 'superior', or 'dysfunctional'. In some cases the test results/scores are placed in a section within the body of the report itself. In reports, the 'test results' section is included as an appendix. It is also not unusual for reports to exclude the actual test data. This is especially the case in medical settings where concise reports are greatly valued. Actual test scores might also be excluded if it is known that the referral source is neither trained in, nor interested in, seeing the actual scores.

The main body of the report is contained in the *impressions and interpretation* section. It

represents an integration of findings based not only on test scores, but also behavioural observations, relevant history, relevant records, and additional available data. The importance of presenting the information according to domains rather than test by test has already been discussed. The selection of domains is based on answering the referral question. If ability/IQ measures have been measured, it is traditional to place these first since they usually provide an important context for understanding most other types of information. Most of the time actual IQ scores are given along with percentiles and intelligence classification (Low Average, Superior, etc.). Some authors might prefer to provide an estimate of the range of possible error of IQ scores by including the Standard error of Measure. In contrast, other authors might consider this to be too technical and test-oriented and decide to omit this information. If there is a chance the IQ scores might be misunderstood, then they are sometimes excluded and only the percentiles and intelligence classifications are given.

Different types of referral categories, along with the specific referral questions, will determine the additional domains to include. For example, when assessing intellectual/achievement types of referrals, important domains might include general cognitive ability, specific strengths and weaknesses, level of achievement, aptitudes, learning style, interests, and possibly vocational interests. A neuropsychological report might not only focus on cognitive abilities and achievement but also learning/memory, language functions, attention, visuoconstructive abilities, executive function, emotional functioning, and potential and strategies for cognitive rehabilitation (Groth-Marnat, 2000).

The most valuable section is usually the *summary and recommendations*. The importance of this section is that sometimes it is the only section read by allied health professionals concerned with time efficiency. The summary provides an opportunity for the practitioner to succinctly state the main conclusions of the report. As indicated previously, the summary section also provides an opportunity to make sure each one of the referral questions have been addressed. The recommendations are an opportunity to provide person-focused suggestions on solving specific problems. A clear research finding is that reports are typically rated as most useful if the recommendations are highly specific rather than general (Ownby, 1990; White et al., 1984). Thus a statement such as the 'client should begin individual psychotherapy' is not as useful as one that states the 'client is likely to benefit most from weekly sessions of individual psychotherapy using strategies to decrease their level of subjective distress, enhance social supports, and increase their level of awareness related to self-defeating patterns in interpersonal relationships'. Once a report has been submitted, follow-up contact with the referral source is advisable in order to provide ongoing feedback related to the accuracy and usefulness of the report as well as help facilitate the actual implementation of the recommendations.

FUTURE PERSPECTIVES AND CONCLUSIONS

The above guidelines and outline for a psychological report may, in some ways, appear as a mechanical process. It should also be stressed that the most successful reports are likely to emerge from clinician–client interactions that are characterized by a high level of involvement and understanding. This is then likely to be reflected in a report that is more full, in depth, and captures the complexity and 'humanness' of the client. Technical skills and mechanical interpretation are no substitute for this process. An additional essential quality is that clinicians are well informed related to the type of problem and overall context the client is functioning in.

Given that there is surprisingly little research on psychological reports, it would be crucial to expand this research base. The most likely avenue would be to investigate the interface between research on clinical judgement, psychometrics, and the ability of clinicians to interface with computer assisted interpretations in such a way as to increase the accuracy of clinician-based judgements. This would need to be continually evaluated against the relative usefulness of reports with various referral sources.

REPORTING TEST RESULTS IN EDUCATION

INTRODUCTION

In this entry we shall discuss both how test reports are currently reported as well as enumerating steps that might be taken to improve reporting still further. To the extent that space allows I will try to show rather than tell, although a combination will be used when that seems helpful. I will span three situations for which test results are reported. These are:

(i) results that are reported to an individual examinee,
(ii) results that are reported to an institution,
(iii) results that are reported for a state or nation.

While all of these situations share a number of common aspects, there is also enough that is unique to justify separate treatment. I shall begin with a statement of purpose, then examine the extent to which these purposes are fulfilled in some representative reports, and then finally will try to extend practice by suggesting modifications that could aid in achieving these goals.

There are essentially four questions that a score report should answer, the first three of which are:

1 What is my score? For individuals this might be a single number or a set of numbers, for institutions or nations a summary statistic or a distribution.
2 How do I compare to others? A fact without context is of little value. A single number tells us nothing without the ancillary knowledge about how everyone else did. Even so-called 'criterion-referenced tests' have latent in them the performance of a reference population. Thus, a 4-minute miler is applauded even if he ran alone on the track, but the 'objective criterion' of

4-minutes gets its meaning from the knowledge of how many have tried to do it and how few have succeeded.

3 How stable is my score? If you stand on a bathroom scale and it reads 100 kg, how much will it change if you get off and then get on again?

While all of these questions are important to answer, this ordering represents the typical priority. Hambleton and Slater (1996) in a survey of educational policy makers support this prioritization. This result was confirmed in subsequent experiments on this same class of test users (Wainer, Hambleton & Meara, 1999). Thus the visual emphasis given to each question should reflect this prioritization. In addition, there is a fourth question, strongly related to the first three, whose answer is too often left implicit,

4 What does my score mean? Obviously, this is a validity question, and its answer depends on the score level, how that score compares with others, and how stable the score is. The precise form of this question varies with who asks it. But the answer is almost always a probability statement. For the individual, the question might specialize to 'Can I get into Princeton?'; for an institution it might become 'How well can this student handle the coursework here?'; and for a national report it often reflects the policy issues that drive the assessment with causal questions like, 'Has the intervention aided minority achievement?'

INDIVIDUAL SCORE REPORTS

Let us consider a score report for a college admissions test that is typical of those provided annually to well more than a million high school students in the United States.

Shown in Exhibit 1 is the first page of a report that is sent to each examinee. The principal individual information is contained in the upper left-hand box. It includes answers to all three

College Admissions Testing Program

Your Scores

Test Date: January 2001

Academic Skills Test	Score	Score Range	Percentiles College-bound Students National	State
Reading	81	77–85	97	97
Math	83	79–86	98	98

What does your score range mean?
No single numerical score can exactly represent your academic skills. If you had taken different editions of the test within a short period of time your performance would probably vary somewhat on the 0 to 90 point scale.

How do you compare with college-bound students?
Percentiles indicate what percentage of test takers earned a score lower than yours. The national percentile for your reading score of 81 is 97, indicating that you did better than 97% of the national group of college-bound students. The national percentile for your math score of 83 is 98, indicating you did better than 98% of the national group of college-bound students.

Did you do better in reading or math?
Your score indicates that you performed similarly on the math test and the reading test.

What's the average reading or math score?
For college-bound students in the class of 1999, the average reading score was 50.5 and the average math score was 51.1.

Will your scores change if you take the test again?
If you take the test again, especially if you study between now and then, your scores may go up.

Among students with reading scores of 81, 63% score lower on a second testing and 37% score the same or higher. On average, a person with a reading score 81 loses 2.1 points.

Among students with math scores of 83, 65% score lower on a second testing and 35% score the same or higher. On average, a person with a math score 83 loses 1.8 points.

Academic Skills Test	Score	Percentiles among college-bound students: National	Among the applicants of the colleges you applied to: Ivy U	Elite C	State U
Reading	**81**	97	47	75	97
Math	**83**	98	57	77	98

How do you compare with college-bound students?
Percentiles indicate what percentage of test takers earned a score lower than yours. The national percentile for your reading score of 81 is 97, indicating that you did better than 97% of the national group of college-bound students. The national percentile for your math score of 83 is 98, indicating you did better than 98% of the national group of college-bound students.

What's the average reading or math score?
For college-bound students in the class of 1999, the average reading score was 50.5 and the average math score was 51.1.

How do you compare with the other seniors who have applied to the same colleges you have?
Your test performance ranks you at:
Ivy U about average among all their applicants,
Elite C among the top quarter of their applicants,
State U among the top 2% of their applicants.

Ivy U accepts about 10% of all applicants
Elite C accepts about 25% of all applicants
State U accepts about 50% of all applicants

Exhibit 2. A modification of the report shown in Exhibit 1.

questions, with little in the way of visual emphasis to their relative importance to the examinee. Just beneath this box are several paragraphs of prose that provide a general discussion of the meaning of the numbers communicated previously.

Beneath this discussion might be a breakdown of the overall performance by the category of questions asked as well as a summary of performance on previous test administrations.

While this report has much to recommend it, there are some changes that could be helpful. In particular, it would seem that two simple modifications ought to be seriously considered. First, keep in mind the priority of the questions asked and make the examinee's scores stand out. Exhibit 2 does this by using a much larger font size for the individual scores. The extra space that this takes up was obtained by moving score stability information to a less prominent position later on in the report. The answers to the second question were specialized in this report to provide the examinee's relative position among all the applicants to the three colleges she applied to. Obviously, if the examinee does not provide college choice information, the report would have to retreat back to comparison groups of convenience. Institutional reports do not suffer from this shortcoming and much more informative displays can result (see Exhibit 3). Evidence to help answer the fourth question is provided in the text, which could be customized for each examinee.

INSTITUTIONAL SCORE REPORTS

Shown in Exhibit 3 is an extract from a typical report sent to colleges describing the performance of an examinee on a college admissions test. This report has much to recommend it from a content point of view, although graphical improvements could provide visual emphasis to those aspects of the report of greatest potential interest to the user. It is noteworthy to see that this report is organized in a way that reflects the priority of interests of the user.

After identifying the examinee, the results start with an answer to the first question by displaying the examinee's scores on each of the subtests and

provide context (question 2) by transforming them into both local and national percentiles. Next they provide an answer to the most important question (4) 'How well can this student handle the coursework here?' by providing the examinee's percentile rank at that institution in each of several programmes of study as well as overall. Then last, the report makes specific projections, helpful for both admissions decisions as well as subsequent guidance decisions, if the student ends up matriculating at this institution. The answer to question (3), score stability, is relegated to another, less central, part of the report.

This report, because of its explicit connection to the criteria of interest to the user, is clearly state-of-the-art. In Exhibit 4 are some suggestions for graphical modifications that might convey these results more efficiently. These changes involve minor typographic changes that emphasize the overall scores and ranks, and ordering the examinee's performance from high to low.

NATIONAL SCORE REPORTS

Shown in Exhibit 5 is a graph that is a central display of the 'State Assessment Report Card' published periodically by the National Assessment of Educational Progress (NAEP). The location of each state tells its relative position and the shading conveys stochastic variability by indicating if the mean score of the state of interest is significantly different than another. Although this display answers questions (2) and (3), remarkably, to find the actual mean score of any state one must return to the component data tables.

An alternative (Exhibit 6), originally proposed by Wainer (1996) and improved upon by Almond et al. (2000), remedies this lack. It also provides a quantitative measure of the size of the difference between states.

CONCLUSIONS

In this entry, examples of what ought to be considered in improving current practice in score reporting have been provided. In addition, there is an attempt to demonstrate how such displays can evolve by making the goals of the report, as well as the order of its priorities, explicit. A single data display cannot do everything equally well. Choices must be made. Improvements for one purpose may represent a reduction in usability for another. The biggest change to current reporting practice that would result from a serious consideration of user needs would be the diminution of priority given to the communication and discussion of score stability. The scores presented must be stable enough for their intended purpose, but beyond that (which could be communicated implicitly) the users typically do not care very much. And, for the most part, most commercial tests have reliabilities (0.90 and above) that are more than enough for their task.

Test results are less likely to be stable enough when test scores are broken up into subscores for diagnostic purposes. When subscores are communicated and there is the clear indication that those subscores are to be used for some sort of remediation, it is the responsibility of the testing organization to be sure that the remediation will not be chasing noise. This means stabilizing the scores somehow (e.g. using empirical Bayes estimates [Thissen & Wainer, 2001]) and communicating clearly how much variability should be expected.

Finally, typography and graphic display seems worthy of some discussion. In the world of

paper-based reports, it has often been important to squeeze everything into a very limited space. This has yielded graceless reports filled with densely printed columns of numbers of varying usefulness wearisome to the eye. Typically, the content of such reports is based upon need and history. Institutional inertia has meant that once material has found its way onto such a report it is very difficult to remove it. With the broad availability of electronic reporting battles to remove long included information need not be fought. Instead material can be organized hierarchically so that the user can access what is required and leave alone what is not – but it is all there. Such a methodology also allows the transmitter of the information, by keeping track of which aspects of the score reports are accessed, to reshape future reports to suit their patterns of use.

RESIDENTIAL AND TREATMENT FACILITIES

INTRODUCTION

During the last decades there has been a trend towards building down inpatient care, but still many persons receive treatment in residential facilities. However, there are few assessment instruments measuring dimensions of such facilities and there are few empirical studies. Assessments of facilities should aim at the three basic questions of whom, what and how: (1) *Who* is the facility serving? (2) *What* kind of treatment are the patients offered? (3) *How* are the patients doing? (Or: What is the success rate of the programme?)

WHO IS THE FACILITY SERVING?

This basic question can be measured by simple aggregate data for patients like age, gender, diagnoses and a global measure of severity of the illness or state of the patient. It might be useful to aggregate data of the following instruments that most often are used to evaluate single patients.

The Health of the Nation Outcome Scales (HoNOS) (Wing et al., 1998) are designed to be rated by the clinician in every day clinical practice. They can be used to get a profile of the patients on twelve key dimensions comprising problems concerning behaviour, self-injury, drinking or drug-taking, cognition, physical illness, psychotic symptoms, depressed mood, relationships, activities of daily living, living conditions and occupation.

The Global Assessment of Functioning Scale (GAF) is used extensively as a global instrument (Endicott et al., 1976). However, it is important to keep in mind that without proper training and monitoring of reliability, the scores may easily

Table 1. Overview of instruments for evaluation of residential and treatment settings

Focus of interest	Instrument	Measures	Filled in by	Unit characterized by
Who are the patients?	HoNOS	Psychiatric problems	Therapist	Aggregate scores
	GAF	Global functioning	Therapist	Aggregate scores
	SCL-90	Distress	Patient	Aggregate scores
What kind of treatment is given?	ESMS	Type of service	Researcher	One form per unit

How successful is the programme?	GAF	Global functioning	Therapist	Aggregate scores
	SCL-90	Distress	Therapist	Aggregate scores
	VSSS	Patient satisfaction	Patients	Aggregate scores

become so inaccurate that they are nearly worthless (Loevdahl & Friis, 1996). To improve reliability, a new version of the scale has been suggested, with separate scales for assessment of severity of symptoms and severity of functional impairment (Goldman et al., 1992).

In many settings, it may also be relevant to add a scale like the SCL-90 (Derogatis et al., 1976) to give a measure of the level of perceived distress. However, this scale is not applicable for the most severely ill patients, like those with chronic psychoses. Many of these patients are either unable to complete the form or tend to score in the range of normal controls.

Karterud et al. (1998) give an example of how such aggregate data can be used to monitor units within a network of day hospitals.

WHAT KIND OF TREATMENT ARE THE PATIENTS OFFERED?

Only recently a systematic description and categorization of facilities has been published. The European Service Mapping Schedule (ESMS) has been developed by an international expert panel to classify the whole range of adult mental health services, including residential units with various intensities and types of care (Johnson et al., 2000). The instrument can be used to describe and study services, as well as differences and gaps in services. This is especially useful for describing and analysing systems of services, but it may also be used for describing and comparing dimensions of individual residential facilities. The map of the service tree has three main branches: residential services, day services and structured activities, and out-patient and community services. Within each branch the services are classified according to characteristics such as acute/non-acute, hospital/non-hospital, time limited/indefinite, mobile/non-mobile and different levels of intensity of services. Characteristics, structure, functions and range of services can be described, and levels of service use can be measured for each type of service. A glossary defines all terms in the instrument so that they can be used in the same way in different studies. A recent study in Spain shows how the instrument can be used and includes a discussion on reliability and validity (Salvador-Carulla et al., 2000).

The International Classification of Mental Health Care (ICMHC) has been developed in a WHO collaborative study (de Jong, 2000). Ten modalities are rated for each module of care (treatment unit) using a 4-point Level of Specialization Scale. The scales are applicable for residential as well as non-residential treatment units and evaluate areas like: relationships, functional assessment, care, activities of daily living, therapeutic interventions, social and interpersonal skills, daily activities, and interventions aimed at family and relatives. The ICMHC gives guidelines on how to identify the smallest functional treatment unit of measurement in the structure of services, which also is useful when using other instruments to assess treatment units.

Treatment philosophy or practice can be measured by giving the Community Program

Philosophy Scales (CPPS) to the staff (Jerrell & Hargreaves, 1991). The CPPS was developed for community treatment teams, and has 20 subscales measuring some general aspects (openness for new ideas, involvement, programme clarity, cohesion, supervision), to what extent the team addresses different needs of the patient, and the team's emphasis on different treatment approaches. Most of the subscales have proved to be reliable and to be applicable also to residential treatment units. A revised and extended version of CPPS is being developed with scales covering additional dimensions of residential treatment.

The Policy and Service Characteristics Inventory (PASCI) is another instrument that can be used to measure policy and characteristics of available services (Timko, 1995). The 140 items are filled-in by a researcher together with an administrator or other responsible staff. PASCI gives nine subscales divided into three groups: requirements for residents' functioning (expectations of functioning, acceptance of problem behaviour), individual freedom and institutional structure (policy choice, resident control, policy clarity and provision of privacy), and provision of services and activities (availability of treatment services, availability of daily living assistance and availability of social-recreational activities). Internal consistency (Cronbach's alpha) and test–retest reliability has been shown to be good or acceptable for most of the subscales.

The psychosocial climate can be measured by questionnaires like the Ward Atmosphere Scale (WAS) (Moos, 1996) or the analogue Community Oriented Program Environment Scale (COPES) (Moos, 1996). Both scales have ten subscales which measure aspects of the following three main areas: Relationship, Personal growth and System maintenance. These scales have several advantages: they can measure both staff and patient perceptions of the climate, and both the real and the ideal setting. As different patient groups prefer and seem to benefit from different types of milieus, such measurements may be important for tailoring the milieu to the needs of specific type of patients (Friis, 1986; Moos, 1996). A limitation is the fact that the scale is difficult or impossible to fill in for very sick patients, and there is a need for six to ten completed forms to form a fairly stable mean score for a unit. Each of the ten subscales is based on items that measure either behaviour (patient or staff) or staff attitude. It is worth noting that while behaviour and staff attitude items usually are strongly positively correlated, this may not always be the case. On wards with severely disturbed patients, one may e.g. find that the higher the level of perceived aggression, the more negative is the attitude toward display of aggression (Roessberg & Friis, 2000). On such wards, the sum of all items in the Anger and aggression subscale may underestimate the level of aggression of the ward. To obtain a more accurate measure it might be necessary to calculate two separate scores, one for aggressive behaviour and one for attitude towards display of aggression.

The WAS and the COPES measure fairly stable characteristics of a treatment milieu (Moos, 1996), what one could term 'the personality of the climate'. We lack good alternatives to measure the more fluctuating states of the climate. Concerning aggression, a possible candidate for measurement of state is the Social Dysfunction and Aggression Scale (SDAS) (Wistedt et al., 1990). The SDAS gives a score for each patient's level of inward and outward aggression. The aggregates of SDAS scores for all patients in a ward are in our experience useful measures to monitor fluctuations in the overall level of aggression in the ward. The SDAS scores can also be used for comparisons of wards.

The number of discrete aggressive events on a ward can be measured by use of the Staff Observation Aggression Scale (SOAS) (Nijman et al., 1999; Palmstierna & Wistedt, 1987). The SOAS may be used for monitoring aggression at a ward. But as the number of aggressive incidents usually is fairly low, the monitoring is sensitive to random variation. However, the SOAS form may help the leaders of the ward to pick up early warning signals of an increase in violence, so they can take necessary steps to avoid an epidemic of violence.

The use of medication can be measured by scoring the types of medication and the dosage for each patient e.g. by use of the ATC and DDD systems (Guidelines for ATC classification and DDD assignment, 1999). As medication may fluctuate during the stay, comparisons between units are most easily made by rating the dosages at a fixed point of time, e.g. at discharge.

Use of restraint and compulsory treatments are obviously important aspects of a unit's treatment programme that should be rated. However, to

our knowledge, there are yet no published instruments that are suitable for this purpose.

Length of stays is also a useful dimension to include in a description or assessment of residential treatment units. Length of stay will reflect the duration of exposure to treatment, but also the role of the unit within the mental health services in the catchment area. Length of stay is most often measured as the mean duration for patients discharged within a specified period of time. In some cases it may be more useful to use the median, as the mean score is much more influenced by outliers such as exceptionally long stays.

Staff/patient ratio, the professional profile of the staff and staff turnover may be other useful characteristics to include in assessments of residential units. These dimensions are important in assessing the resources available and the possibility for continuity of care.

Physical dimensions of the facilities may be important, but are very seldom measured. One of the few instruments here is Physical and Architectural Characteristics Inventory (PACI) with assessment of seven dimensions such as community accessibility, physical features that add convenience, aid recreation and provide support for patients, and space for patient and staff function (Timko, 1996).

TO WHAT EXTENT DOES THE UNIT SUCCEED IN HELPING PATIENTS IMPROVE?

In a previous section, we mentioned that aggregate data can be used to give an overall description of the group of patients admitted to a unit. In the same way aggregate data of, e.g., changes in severity of symptoms and functional impairment will give an overall description of the unit's success in helping patients improve. GAF or S-GAF give a global measure that can be used across all patient groups, while the SCL-90 can be relevant as a measure of improvement in the level of perceived distress. However, as mentioned above, this scale is not applicable for the most severely ill patients.

For most diagnostic groups of patients, there are several well-established questionnaires and rating scales that may give aggregate scores to be used in assessment of treatment success. Other entries of this encyclopedia address such instruments for specific patient groups.

User satisfaction with different aspects of the treatment has become increasingly emphasized as an important measure of the quality of a treatment programme. Several instruments in the form of questionnaires or interviews are available and have been used also regarding residential treatment (Ruggeri, 1996). One of the more widely used is the Verona Service Satisfaction Scale (VSSS) (Ruggeri & Dall'Agnola, 1993). This is a questionnaire covering overall satisfaction, the skills and behaviour of the staff, information, access, efficacy, types of intervention and relative's involvement.

FUTURE PERSPECTIVES AND CONCLUSIONS

Through the last decades, the growing emphasis on non-residential mental health services has created more interest for research on such services compared to research on residential treatment. This is also reflected by the fact that there are few instruments in widespread use for assessment of residential facilities, even if such facilities still are important corner stones in mental health services for persons with severe mental disorders. The growing number of new instruments for assessment of residential and other treatment units (see Table 1) may be a signal of new interest in residential treatment as a part of mental health services research and evaluation. Further development of and experience with such instruments are important steps in this development and may increase our possibility to understand the complexity of residential treatment and its contribution within the mental health services.

RISK AND PREVENTION IN WORK AND ORGANIZATIONAL SETTINGS

INTRODUCTION

Occupational safety thinking has undergone considerable extensions of scope during the last years. The focus shifted from personal characteristics as source of risk to the influence of work place as source of risk to organizational factors (Sheehy & Chapman, 1987). Prevention of occupational accidents and safeguarding of employee health as well as protection of environment have become

critical elements within a holistic framework of comprehensive 'integrated safety management' strategies (Zimolong, 1996). According to Hoyos and Ruppert (1993) safety can be achieved through joint and continuous efforts of management and employees in conjunction with requisite technical installations and safeguards. Thus, attention is directed to aspects of the encompassing organizational system instead of only focusing on individual workers and their work place but it remains centred on the focal organization.

Concepts in this field mainly theorize unsafe behaviour of single persons, either from a cognitive, motivational or learning perspective. Cognitive models of unsafe or risk-taking behaviour assume that people have a target level of risk to which they adapt their individual behaviour like in the risk homeostasis theory (Wilde, 1982), or that people act not as decision makers that makes them run risks (Wagenaar, 1992). According to Trimpop (1996) the motivation to perform safely is mainly influenced by three motives: to prevent a personal injury, to minimize efforts for work and to design work variable. People then calculate cost and benefits of future behaviour including emotional as well as cognitive aspects. Learning theories (Musahl, 1996) centre past behaviour, the probability of unsafe behaviour in the future increases as long as unsafe behaviour in the past did not lead to accidents. Recent models are expanded to organizational factors assuming that working conditions themselves can lead to accidents or increase the accident risk by so called error enforcing conditions (Reason, 1990).

Feed-forward strategies are mainly based on risk or hazard assessment. Feedback strategies are mainly based on accident and injury rates gathered from insurance statistics. An accident is often defined by three or more days of absence from work. Less than three days is defined as near-accident and usually no report has to be submitted.

Prevention strategies either focus on the individual, as personnel selection, training, and certain reward systems, or on ergonomic design. Münsterberg's early attempts to reduce accidents of 'motormen in street railway transportation' (Münsterberg, 1913: 63) and later of ship officers through respective selection techniques based on laboratory experiments are well known early approaches to occupational accident prevention. Another example of selection methods is the cognitive failure questionnaire (Broadbent, 1982), developed to detect accident-prone people. Empirical data again do not show definite results (Klumb, 1995). Training methods for safe behaviour aim at behavioural change through extending knowledge or competence as safety talks and safety discussion do (Fahlbruch, 1998). Reward systems aim either at the individual or a team, examples are bonus systems related to safety competitions among different work units. Preventions that aim at improving the ergonomic design state a priority of collective protection over an individual one. Other kinds of intervention focus on participation of workers in quality or safety circles. Recently the institutionalization of safety management systems or integrated HSE management systems is asked for. The perceived importance of leadership for safety leads to the involvement of managers and supervisors as well as to specific training for the management (Zimolong, 1995).

SYSTEM SAFETY

Disasters like the Chernobyl accident or major train accidents, like Clapham Junction or Eschede, lead to a different perspective on safety: accidents are considered as loss of control of the whole system with drastic negative consequences for people and environment. Such accidents are usually the case for high-hazard industries (Fahlbruch & Wilpert, 1999). It is the domain of such large-scale, low-risk, high-hazard organizations and their complete and disastrous breakdowns for which Fahlbruch and Wilpert (1999) reserve the notion of 'system safety' which they define 'as a quality of a system that allows the system to function without major breakdowns under predetermined conditions with an acceptable minimum of accidental loss and unintended harm to the organization and its environment' (p. 56). One reason is the design principle, the 'defence-in-depth' design, which is introduced in these kind of industries.

Accident causation theories are the main theoretical background in this field. Recent models are based on the concept of barriers which should protect objects from sources of danger. Reason (1990) extends his accident causation theory to several barriers within the organization. He assumes that in high-hazard

organizations, one unsafe act by an operator cannot cause a system's breakdown because of the defence-in-depth designs and that additional weaknesses in the organization are necessary for the occurrence of accidents. He introduces the concept of active and latent failure. Active failures are associated with the 'front-line' operators at the sharp end and trigger immediate adverse effects. Latent failures are associated with persons at the blunt end who are not involved in 'front-line' activities, e.g. decision makers. Their erroneous actions remain unrecognized for a long time period weakening the system functions like resident pathogens. Therefore, fallible decisions by top level management, deficiencies by line management, psychological precursors of unsafe acts, unsafe acts of operators as well as inadequate system defences together create a limited window for an accident occurrence path. Reason identifies eleven general failure types, latent failure domains: hardware defects, inappropriate design, poor maintenance management, poor operating procedure, error enforcing conditions, poor housekeeping, incompatible goals, communicational failures, organizational failures, inadequate training and inadequate defences (Groeneweg, 1992). Recently, the importance of inter-organizational factors as contributing to the occurrence of accidents is stated (Wilpert & Fahlbruch, 1998).

Assessment of risk is again conducted in a feed-forward or feedback way. Probabilistic risk or safety assessment methods serve to foresee possible accidents and to identify possible weaknesses in order to improve the system defences by countermeasures. This is a field mainly dominated by engineers and therefore the methods are based mainly on the functionality of the system. Main feedback strategies can be seen in accident analysis aiming at identifying factors that contributed to the occurrence of the given event. For these identified factors including weaknesses within the organization safety intervention/measurements have to be generated. Results of event analyses then lead to the learning of the organization with the aim to improve reliability and safety. Therefore, the systematical analysis of events can be seen as the starting point for learning from operational experience, and valid methodologies for event analysis are important for building a valid basis for the subsequent processing of learning. Opportunities for event analysis methodologies are seen in the possible prevention of future events, in the identification of potential organizational weaknesses, in the chance for systematic modelling of organizational context and interactions as well as in a possible stimulation of systematic thinking.

Prevention aims either at improving the technical system in the direction of less error proneness or at introducing error management, in which errors are seen as a learning chance for the organization (Frese, 1995), or at the introduction of organizational learning systems which are fed by the results of analyses of events and near-accidents. Examples of an organizational learning system are event databases as Synergi (Aase & Ringstad, 2002).

SAFETY CULTURE

Since the Chernobyl accident the term safety culture has been introduced. Safety culture is seen as a holistic concept and has tremendously stimulated practice and research in the field of high-hazard systems. The concept of safety culture serves also as an effective vehicle to promote theorizing and empirical research by directing the attention to wider managerial, organizational and inter-organizational issues of safety. But there is still a lack in common understanding of what safety culture means. Definitions range from cognitive aspects over shared value and norms to behaviour.

Measurement of safety culture is conducted either by safety climate or safety culture questionnaires, interviews, document analyses and observations (for an overview, see Büttner, Fahlbruch & Wilpert, 1999 or Guldenmund, 2000). Prevention is meant to increase systemic thinking and questioning attitude and mainly mediated by training.

INSTRUMENTS

In the occupational safety area, risk assessment is mainly done again by risk or hazard analysis. Methods are often practical orientated designed for certain industries focusing on factors which were causal in past accidents, like missing protection equipment or falling things. In recent days, long-term health hazards as well as sources

of psychological strain are often integrated in the analyses. But it seems that there is a lack in proved or evaluated instruments; the safety diagnosis questionnaire (Hoyos & Ruppert, 1993) can be seen as an exception. This questionnaire combines personal, work place and organizational factors and is closely related to methods of work or task analysis. Feedback analysis is mainly done without systematic methods. The TOR method (Technique of Operations Review – Weaver, 1973) can be stated as an exception. After an information search the TOR scheme with management categories mainly is used to identify causes by answering questions. But usually only categorization according to causal categories instead of systematic analysis methods is conducted.

In the system safety field, usually quantitative methods as PSA are used for feed-forward analysis, but in recent times more qualitative approaches gain ground, trying to introduce management and cultural aspects as well (Kirwan, 1998). Human behaviour is included in these assessments by modelling human reliability. Human reliability assessment (HRA) methods can be categorized according to Giesa (1996) into decomposition methods, e.g. Technique for Human Error Rate Prediction – THERP (Swain & Guttmann, 1983), time-reliability correlations, e.g. Human Cognitive Reliability – HCR (Hannaman, Spurgin & Lukic, 1984), and structured expert assessments, e.g. Success Likelihood Index Method – SLIM (Embrey, Humphreys, Rosa, Kirwan & Rea, 1984). For an overview and evaluation of different HRA techniques, see Kirwan (1996, 1997 a, b, c & d) and Kirwan, Kennedy, Taylor-Adams, and Lambert (1997). The authors used evaluative criteria like accuracy and precision as well as optimism/pessimism of estimates and judgement consistency. They conclude that future validation of the methods in use should be expanded to cover the entire process of task and error analysis and address the problem of internal validity as well.

Existing feedback methods in the field of system safety mainly focus on individual, technical and organizational failures as do ASSET (Assessment of Safety Significant Event Teams – IAEA, 1991, 1994a), CREAM (Cognitive Error and Reliability Analysis Method – Hollnagel, 1998) or MORT (Management Oversight and Risk Tree – Johnson, 1980). This can be seen as a shortcoming for the above reasons (Fahlbruch, 2000). An exception is the event analysis methodology Safety through Organizational Learning – SOL (Fahlbruch & Wilpert, 1997), which takes individual, group, organizational, inter-organizational as well as technical factors into account and which was also evaluated for its support of analysts (for a review of analysis methods see Benner, 1985; Becker et al., 1996; Fahlbruch, 2000).

There exist no complete and accepted instruments yet for assessing safety culture (Fahlbruch & Wilpert, 2000). First approaches are questionnaires of safety climate or safety culture like the ASCOT methodology for nuclear power plants (IAEA, 1994b).

FUTURE PERSPECTIVES AND CONCLUSIONS

In conclusion, it can be stated that the approaches of occupational safety are characterized by the following advantages: in this field exists a great variety of qualitative and quantitative prevention orientated measurement methods. Theorizing, measurement and interventions aim at integrating Human Resource Management. A certain disadvantage may still remain in the existing orientation towards the man–machine interaction, despite the efforts to consider also organizational factors. The system safety approaches are characterized by the following advantages: efforts are made to learn from experience, whereas experience from the whole organization is gathered, event analysis methods enhance the search for organizational factors and thus, the concentration on the man–machine interface could be overcome. But there are also disadvantages: system safety approaches still have a lack of diagnostic methods for safety status, nearly no qualitative prevention oriented measurement can be found and there is no systematic integration of human resource management knowledge. Furthermore, the interaction between different organizations is still not fully taken into account. Analyses and interventions are usually restricted by the borders of the organization, not taking inter-organizational issues into account.

Safety culture can be seen as the future construct for both fields, the occupational safety

and the system safety field, but there is still the need for further theoretical work and the development of adequate assessment tools, because existing ones are still faced with shortcomings like remaining in the level of cognitive aspects or lack of evaluation (Fahlbruch & Wilpert, 2000).

SELF, THE (GENERAL)

INTRODUCTION

The self-system is very complex. It has become usual to distinguish between the self as subject (as Ego or I) and the self as object. The self-system assessment has been restricted to the latter. However, even when the self is considered as an object there are various domains to be assessed: the self as self-concept or, in general, self-representation, including schemas, contents and the structure of the self-knowledge (usually, with specific instruments to assess them); the self as a process, as a set of cognitive and behavioural activities, or instances related to oneself (mainly, assessed by techniques or procedures of functional analysis).

SOURCES IN SELF-THEORIES

Self-system assessment emerged originally rooted in phenomenological theories with emphasis on the self-concept. In these theories, the self-concept and the self-consciousness were assumed to govern the behaviour, to account for its consistencies, and, hence, to provide psychology with valid scientific explanations and predictions. However, in spite of their historical background, the instruments for assessment have become largely independent from the theories in which they are inspired, and are often used within other theoretical frames, e.g. trait models or in a highly atheoretical practice, where the self-concept is only assessed and described, but not alleged as a causal or explanatory factor.

A wide array of assessment procedures and tools have been designed. The most common procedures of self-concept assessment are based on self-reports, as rating scales, questionnaires, inventories, and adjective checklists. There are also other well known techniques, but rarely used in other fields, as Q-sort, semantic differential, grid-technique related to personal constructs, open-ended statements, and projective techniques. Most of the standardized instruments are supposed to be administered not only with a fixed content of items, but also by a specific procedure. Nevertheless, in some cases, the assessor can use an established set of items (adjectives, statements) in a format not previously foreseen by its designers, i.e. Q-sort.

Some more general personality repertoires and questionnaires include a scale or factor of the self-concept or of a quality of it, for instance the 'strength of the self'. Here, only specific devices are reported. Among the best known and popular instruments, the reader can find those that, whether explicitly linked to self-theories or not, rely on self-reports as the data that provide objective bases for inferences about concepts, schemas, attitudes and feelings about oneself.

STANDARDIZED INSTRUMENTS TO ASSESS THE SELF-CONCEPT

One of the first attempts to cover the domain of self-description was made by Sheerer (1949). This author extracted from protocols of cases at a counselling centre all the relevant statements for attitudes either to oneself or to other people. These statements served as input for a 101-item rating scale, that lies on the basis of other similar scales.

A similar attempt was made by Butler and Haig (1954) in a set of one-hundred self-referent items. Inspired in Carl Rogers' model of the self, they aimed to pinpoint an index of self-regard and self-acceptance in the correlation between the real and ideal self. Butler and Haig's list has been the source of the item content for various instruments. These items; anyway, can be assumed in other formats, for instance, those of scale, inventory, or questionnaire, subjects having only to answer yes or no. On the other hand, there are still other instruments based on discrepancy values taken as an index of self-regard or self-esteem. Thus, the *Index of Adjustment and Values* (IAV) (Bills, 1958) intends to provide a self-minus-ideal discrepancy score. It consists of a checklist with 49 adjectives reflecting desiderable or undesiderable traits. Discrepancy scores are obtained through the contrast of the three columns formed with the answers to these questions: (1) How often are you this way? (2) How do you feel about being this way? (3) How long would you like to be this way?

The traditional assessment of the self-system has oscillated between a global approach, as an unidimensional entity, and a search for specific measures related to various facets or dimensions of the self. The continuum from general to specific assessment instruments of the self displays a spectrum from mono-trait to multi-trait approaches. Global scales are unidimensional, while specific ones assume that the self construct is too wide and that other more precise scales or subscales are needed in order to get an accurate assessment and prediction. A favourite topic has been the self-esteem and its analogues: self-acceptance, self-evaluation. But the self-esteem itself can be considered as global in contrast with more specific domains of the self-evaluation: academic, corporal, or moral domains.

At the global pole of the continuum there are repertoires and questionnaires that, like the *Children's Self-Concept Scale* (PH), by Piers–Harris (1969), and the *Tennessee Self-Concept Scale* (TSCS), by Fitts (1965), try to cover a wide array of contents. PH presents a set of 80 declarative sentences about 'the way I feel about myself' to be marked yes or no. Six factors have been found and can be measured by PH: behaviour, intellectual and school status, physical appearance and attributes, anxiety, popularity, and happiness (or satisfaction). So, it provides a portrait of self-knowledge and not only of self-esteem. The TSCS has two forms: (a) a brief Counselling Form; and (b) a longer Clinical and Research Form. This longer form consists of 100 self-descriptive statements which subjects may or may not endorse, to portray their own picture of themselves. Its age of application ranges from 12 to late adulthood; and it is presumed to tap also the whole range of psychological adjustment: from well adapted people to psychotic patients. The TSCS provides scores on: identity, self-satisfaction, the physical self, the moral self, the personal self, the family self, and the social self.

There are also instruments designed to assess self-esteem. Thus, the *Coopersmith Self-Esteem Inventory* (SEI) (Coopersmith, 1967), whose published version consists of 58 items with an age range of pertinence from 10 to 16; and Rosenberg's Self-Esteem Scale, constructed as a brief and unidimensional scale (10 statements) to explore a global evaluative self-regard (Rosenberg, 1965). There are still more specific scales, devoted to a very concrete aspect of the self-image and the self-evaluation. This is the case of a scale designed by Lerner, Orlos and Knapp (1976) to assess how people evaluate themselves and how much they are satisfied with their physical appeal and effectiveness. Although designed for late adolescence, this scale also fits childhood and adulthood. As the self is a salient construct during the adolescence, it has been especially explored along this age; many scales and inventories have been designed or tested for late childhood and adolescence.

PROBLEMATIC ISSUES IN THE ASSESSMENT OF THE SELF-SYSTEM

Traditional assessment was: (1) limited to internal, private, non-directly observed, and dispositional or

trait-like structures; and (2) related to cognitions, judgements and attitudes towards oneself. The assessment heavily relied upon inferences from subjective self-reports. Hence, the psychometric assessment of the self-concept had to face problems of reliability and validity similar to those found in the assessment of cognitive and affective structures. When individuals are self-concerned, biases of social desiderability, acquiescence or, on the contrary, refusal, and, in general, distortion, come to the stage. These problems in the assessment of self-system are not unique in kind, but they are especially uneasy to deal with.

At present, classical scales, inventories and questionnaires to assess self-esteem and self-concept have come under strong criticism. Most reviewers of the psychometric approach to self-concept by standardized instruments (Crowne & Stephens, 1961; Lowe, 1961; Wylie, 1974) have been not only dissapointed, but very critical. Critics emphasize that self-concept assessment and research lack conceptual clarity and are plagued with artefactual biases and shortcomings.

There are no satisfactory working definitions of the self-concept and of other self-related constructs involved in psychometrical tools. Most definitions of the self-concept are highly abstract to be empirically testable. Semantic ambiguity precludes rigorous tests of crucial hypotheses. In short: over-generalized self-referent constructs, such as self-concept, not to say self-consistency or self-actualization, and their presumed markers are not useful; they do not contribute to explain and to predict the behaviour; and they must be replaced by other more fruitful constructs leading to more scientific tools.

The self-concept is neither an entity, nor a unique concept. Actually, it consists of a set of self-oriented concepts, a variety of mental representations about oneself. Moreover, the self-system appears to be internally complex and multi-faceted. So, a multitrait model is needed, where each aspect calls for a related instrument or scale. Actually, many instances have been targets of specifically designed assessment tools, each of them tapping one dimension that is presumably relevant for the prediction of behaviour. Therefore, it is brought to psychometric scrutiny: self-attributions, self-monitoring, self-awareness, self-talk, self-presentation, self-disclosure, self-enhancement, self-criticism, self-worth.

This view of the self-system, as a multiple, complex, and multidimensional set of components, could be integrated in a theoretical approach in which a hierarchical organization is proposed. Thus, it has a core nucleus and several peripheral elements (L'Ecuyer, 1978). In such hierarchy, theory holds together various components, whereas empirical research and assessment aim to specify concrete elements in an approach that can meet (so it is expected) the requirements of traditional psychometrics.

FROM PSYCHOMETRIC TOOLS TO BEHAVIOURAL ASSESSMENT

In spite of endeavours to restore it, psychometrical assessment and its instruments, mainly based on insight, self-reports and Q (questionnaire) data, has remained under suspicion. Assessors have turned to more reliable and objective procedures, those of a behavioural analysis. In this shift, the self-system is considered and assessed no more according to the phenomenal field of the subject experience, but in terms of the observer's objective categories. So, research and assessment have been redirected to chains of behaviour with a high commitment of the self-system.

The self-system consists not only of private events, but also of overt behaviours that can be observed. The self-related behaviour is a class of behaviour; and the self-system may and must be seen as a pattern of self-referent behaviour. More precisely, much of the human behaviour, in fact any purposive behaviour, is mediated by self-related processes. Thus, coping overt behaviour could be considered as a self-protective action, hence as a part of self-related activity. Models by Bandura (1977) and by Kanfer and Karoly (1972), that point to self-regulation as an intrinsic element of goal-directed behaviour, make possible a behavioural and functional analysis of the self-system anchored in motor and verbal activity. The self-system is heavily involved in goal-directed action (Bandura, 1989), where human agency comes to overt motor or verbal behaviour through self-related instances and processes: self-observation, self-evaluation, and self-reinforcement.

In this analysis, the self-system is more than a self-concept or a self-consciousness, that are private inferred instances of it. The self-system is not only

a multi-faceted structure, as it is widely recognized, but also a behavioural set of ongoing processes, displayed in a stream of activities from self-perceiving and self-knowing to self-reinforcing, self-talking, and self-helping. It is a functional system as well: it contributes to protect the individual by coping with adverse events and, overall, to adjust the person to the environment and to provide an hedonic positive balance. The challenge for the assessor is to objectively grasp such instances and functions of the self-system with techniques able to produce L (life) and T (test) data.

BEHAVIOURAL TECHNIQUES AND PROCEDURES

According to the principles of behavioural assessment, the techniques and procedures to assess the self-system, i.e. self-related behaviour, are not specific. They are subjected to common tenets and methodological requirements of this kind of analysis. General procedures of behavioural assessment are valid, of course, in self-related behaviour patterns and/or self-oriented qualities of behaviour, even when research is focused on self-structures and processes that are not directly but only indirectly observed and inferred.

Many observable self-referent behaviours do not raise any problem to be classified, assessed, and measured: self-caring, self-talking in loud voice, self-injuries, and self-aggression (Iwata, Dorsey, Slifer & Bauman, 1994; Pelios, Morren, Tesch & Axelroad, 1999). In general, the occurrence and qualities of overt self-behaviour are easy to assess. They do not pose major problems of coding and recording.

The challenge arises when private activity, like self-attention or self-evaluation, or less concrete but objective qualities across behaviours, as self-regulation (Taylor & O'Reilly, 1997), must be assessed. The best option tries to turn such behavioural instances in operations either of the observer or of the subjects. There are aspects of behaviour where the task is to experiment rather than to assess. Namely experimenting is probably the best way of assessing. Thus, for instance, researchers on objective self-awareness and self-attention have proceeded in an approach where the assessment is not aside from experimental manipulation (Duval & Wicklund, 1972). Some simple devices play a salient role in controlled, experimental or non-experimental assessment situations, e.g. the use of mirrors. From Narcissus, natural or artificial mirrors have played a conspicuous role in physical self-regard, self-image, and self-evaluation. Self-directed behaviours in the presence of mirrors yield direct data for inferring self-recognition. Modern technology still provides other tools, such as audiotape and videotape, with or without subjects' awareness of having been recorded.

To move body parts (e.g. head, arms, legs, right, left) with or without verbal instructions in presence of mirrors is highly useful in the study of the ontogeny of self-recognition in childhood, when self-system begins to develop a physical self-image. An image from which the child will later abstract a generalized self and a conscious knowledge of himself, through an on-going task of integration of increasingly wider sets of information inputs.

Such is also the case of techniques based on the self/others contrast: actor/observer, insider/outsider, inward/outward, self/others' attributions, self/other agreement or discrepancy, to see one-self as/or not as others see us (Horowitz, 1998; Ogilvie, Fleming & Pennell, 1998). These techniques are widely used in the assessment of self-schemas: cognitive structures that contain generic knowledge about the self (Cash & Labarge, 1996; Muran, Samstag, Segal & Winston, 1998; Sheeran & Orbell, 2000). In settings where potential self-related stimuli are presented to the subject, there are indexes of presence of self-related schemas: in reaction time, speed of processing, accessibility in memory retrieval, salience, readiness, and ability to categorize behaviours along certain dimensions, richness and complexity of self-related descriptions when compared with others' descriptions (Rogers, Kuiper & Kirker, 1977; Rogers, Rogers & Kuiper, 1979).

INTEGRATION OF APPROACHES

Although well founded on integrative tendencies of our time, it is ironic that classical procedures for self-concept assessment have come again in behavioural assessment. In fact, they never disappeared. Forced-choice techniques, like Q sort and grid format, seem to assure a more objective account for the self-report and for the elicitation of personal constructs. The main point, however, from the behavioural approach is that objectivity is searched not only through techniques of data

collecting, but also chiefly through data processing. Data collected with a repertory grid are submitted to qualitative analysis, as well as to quantitative recording and to statistical scrutiny (Feixas & Villegas, 1990).

Discrepancy or congruence between real/ideal scores (or other/self scores) also come back, as a marker of an evaluative process, that may be only implicit in the subject's awareness. Thus, it is presumed that phenomenological subjectivity biases could be eschewed by purely objective comparison between two sets of statements (Fierro, 1986).

Not only classical procedures, also scales thorougly akin to traditional ones, have been designed to serve to a behavioural and objective approach. This is the case of the well-known *Self-Monitoring Scale*, by Snyder (1986), with 25 items. Monitoring refers to the degree to which individuals are sensitive to the demands of concrete situations as well as to their own expressive behaviour in those settings. In a similar vein, Scheier and Carver (1985) have designed a *Self-Consciousness Scale*, that consists of 22 items distributed in three subscales: public, private, and social consciousness.

FUTURE PERSPECTIVES

The present focus of self-psychology on self-construction and self-narratives (Freeman, 1993) invites to foresee a development of behavioural assessment of self-system along the promising way of an analysis of autobiographical materials and personal documents. This approach was originally linked either to a dynamic conception or to an idiographical study. Nowadays, however, the textual analysis of spontaneous autobiographical documents, such as memories, diaries, letters, is an objective procedure to assess the self-system and to infer basic laws concerning not only contents (episodic, ideologic contents), but chiefly formal aspects: clarity, certainty, saliency, and (un)stability of one's own descriptions along the time. Personal self-descriptive texts are first order sources to have a look into personal self-schemas and scripts (in the sense of social psychology), i.e. into explicit or implicit narratives and representations of oneself. From these sources come to light the features, the structure, and the ontogenesis of the self-system: how people perceive themselves, and how they have come to their self-perception (Clarke, 1995).

When there are not such previous texts, the assesser can ask the person to write down autobiographical accounts for a certain amount of time with specific instructions. These accounts may refer to current or past events and experiences belonging to personal memory. Thus, very long-term samples of behaviour can be gathered to grasp people's representations of their life-course patterns across various time scales. In this context, traditional repertoires and inventories of autobiographical memory (e.g. Siegel, 1956) can still be useful for the assessment of the life story, as well as of the self-system.

CONCLUSIONS

Today and in the future, verbal behaviour in self-reporting is likely to remain at the very centre of the assessment of the self-system even within a behavioural approach. However, the behavioural assessment differs from the traditional in its theoretical framework and its use of the rules for inference. Self-reports are weighted as overt behaviours rather than as signs of internal structures. They are taken as a representative sampling of a behaviour class. Finally, the analysis of those self-descriptive statements proceeds from the point of view of an external observer, not from the insight perspective of subjects. When the behavioural assessor uses classical procedures and/or scales, he assumes that it is possible for an objective practice to collect self-reported data and to restate them through analysis techniques similar to those used in the study of texts and verbal discourse.

The key point for an objective assessment of the self-system is a shift from a construct oriented to a behavioural oriented approach. This is anchored in scientific or technical operations that go beyond assessment, although bounded to if: either in a research process, where the assessment is an instance among others, ideally experimental control and inference; or within clinical and intervention settings, where the assessment is a tool at the service of behavioural therapy or modification.

Personality Assessment (General), Theoretical Perspective: Constructivism

SELF-CONTROL

INTRODUCTION

Self-control skills consist of self-monitoring, self-evaluation, and self-administered reinforcement. Self-control is also referred to as self-instruction, self-management, learned resourcefulness, lifestyle organization, and controlled reinforcement is delayed or absent. There are at least four self-report instruments that have been developed to assess self-control skills. Some instruments measure the components of self-control and related skills while others measure behavioural outcomes of self-control. The psychometric characteristics of each instrument will be summarized and recommendations for future instrument development will be discussed.

ASSESSMENT OF SELF-CONTROL

Kanfer (1970, 1977; Kanfer & Karoly, 1972) defined self-control as a repertoire of three self-regulating behaviours including self-monitoring, self-evaluation, and self-reinforcement. According to this definition, the individual monitors a behaviour targeted for change or maintenance. The target behaviour can be overt (e.g. eating) or covert (e.g. thoughts and emotions). The individual then compares the target behaviour to an internalized standard and identifies discrepancies. Based on this comparison, the individual engages in self-reinforcement or self-punishment, which subsequently influences whether further self-monitoring and self-evaluation will occur and whether the target behaviour is modified or maintained. Self-control skills are deemed essential when environmentally controlled reinforcement is delayed or absent.

Self-control is achieved when the individual is able to initiate and persist in a low probability target behaviour (e.g. exercising) as opposed to a competing higher probability behaviour (e.g. watching television). Also, the target behaviour must be maintained without immediate environmental reinforcement. For example, exercising regularly on one's own reflects self-control, whereas exercising only when a coach is prodding, praising, or criticizing does not.

Various definitions of self-control and related constructs have been proposed that differ from that originally proposed by Kanfer. Alternative constructs that have appeared in the self-control literature include self-regulation, self-instruction, lifestyle organization, and learned resourcefulness (see Table 1).

Table 1. Construct definitions

Construct	Definition
Self-control	Applying the processes of self-monitoring, self-evaluation, and self-reinforcement to alter the probability of a response in the relative absence of immediate external support.[a]
Self-instruction	Applying alternative, specific, coping self-statements to the solution of each phase during the solution of a problem.[b]
Self-regulation	Applying the processes of self-monitoring, self-evaluation, self-reinforcement, as well as self-efficacy, to the mediation of most external influences and the motivation of purposeful action.[c]
Lifestyle organization	Setting goals for oneself and then systematically using cognitive and behavioural strategies to reach those goals.[d]
Learned resourcefulness	A personality repertoire consisting of beliefs and self-control skills and behaviours.[e]

[a]Rehm, 1977 (p. 790). [b]Meichenbaum, 1985 (p. 69). [c]Bandura, 1991 (p. 248). [d]Williams et al., 1992 (p. 217). [e]Rosenbaum, 1990 (p. 14).

Self-regulation (Bandura, 1986, 1991; Kanfer & Schefft, 1988) consists of the three self-control behaviours proposed by Kanfer (i.e. self-monitoring, self-evaluation, self-reinforcement), as well as self-efficacy beliefs. Self-efficacy refers to an individual's belief about one's personal effectiveness and, according to Bandura (1991), these beliefs influence whether and in what manner self-control will be implemented.

Self-instruction (Meichenbaum, 1977) refers to the internalization of self-directive speech and involves self-monitoring of self-statements and the use of alternative, self-reinforcing statements. Unlike Kanfer's conceptualization of self-control, however, self-instruction does not involve the evaluation of one's behaviour according to internalized standards.

Lifestyle organization is defined as setting 'goals for oneself and then systematically using cognitive and behavioural strategies to reach those goals' (Williams, Moore, Pettibone & Thomas, 1992: 217). This conceptualization appears to implicitly incorporate Kanfer's three self-directive aspects of self-control including self-monitoring, self-evaluation, and self-reinforcement. Lifestyle organization also refers to other cognitive and behavioural strategies including awareness of lifetime goals and solicitation of feedback from others.

Learned resourcefulness (Rosenbaum, 1990) refers to a constellation of cognitive and behavioural responses, or coping skills, that are somewhat related to Kanfer's concept of self-control. The Self-Control Schedule (SCS) was developed by Rosenbaum (1980) to measure learned resourcefulness and the SCS has accrued strong support for its construct validity (M. Rosenbaum, personal communication, November 25, 1999). Rosenbaum (1990) distinguished between self-control as representing primary cognitive responses and learned resourcefulness as a related but distinct personality repertoire. Due to this distinction, the SCS will not be reviewed in this entry and will be discussed only in reference to its use in psychometric evaluations of other self-control measures.

For the purposes of this entry, self-control will be understood in terms of Kanfer's three-component model. Kanfer's conceptualization of self-control provides a parsimonious and clearly delineated construct. As described earlier, each component of self-control is inextricably linked to the other two in the performance of a targeted behaviour that is not subject to immediate environmental reinforcement. Kanfer's model is extensively cited and is widely recognized as fundamental in the assessment of self-control (Brandon, Oescher & Loftin, 1990; Rehm, Kornblith, O'Hara, Lamparski, Romano & Volkin, 1981; Rosenbaum, 1980) and in the training of self-control skills (Febbraro & Clum, 1998).

MEASURES

Four self-report measures designed to assess self-control as defined by Kanfer's three-component model are described in Table 2 in the order in which they were published. Each of these measures was developed for use among adults and adolescents.

Table 2. Psychometric evaluation of self-control questionnaires

	Psychometric evaluation			
Measure	Content validity	Construct validity	Convergent validity	Reliability
SCQ	Rehm et al., 1981	Rehm & Rokke, 1988 Rude, 1989	Rosenbaum, 1980	O'Hara et al., 1982 Rude, 1989
FSRQ	Heiby, 1982	Heiby & Campos, 1986 Wagner et al., 1988	Heiby, 1982 Heiby, 1983a	Heiby, 1982 Heiby, 1983a
SCQ-Brandon	Brandon et al., 1990	Brandon et al., 1990	Brandon et al., 1990	Brandon et al., 1990
LSA	Williams et al., 1992	Williams et al., 1992	Williams et al., 1992	Williams et al., 1992

Note: References appearing in the content validity column are the original publications for each measure.
Selected summary articles are included in the construct validity column. Refer to text for complete references.

The Self-Control Questionnaire (SCQ)

The SCQ (Rehm et al., 1981) consists of 40 items rated on a 5-point scale. Total SCQ scores range from 0 to 160. No norms or cutoff scores are available.

Reliability

Psychometric studies of the SCQ have reported high internal consistency and stability, with Cronbach's coefficient alphas ranging from 0.69 (Rude, 1989) to 0.88 (O'Hara, Rehm & Campbell, 1982) and 5-week test–retest reliability estimated at 0.86 (O'Hara et al., 1982).

Content Validity

Content validity of the SCQ is difficult to ascertain because details concerning its construction are unavailable. The SCQ, however, is described as rationally derived (Rehm & Rokke, 1988) and has been used to assess the effectiveness of Fuchs and Rehm's (1977) self-control behaviour therapy for depression. Based on this self-control treatment model, the SCQ measures deficits in self-monitoring (i.e. self-monitoring of negative events; selective monitoring of immediate versus delayed consequences of behaviour), self-evaluation (i.e. exceedingly demanding standards; inaccurate perceptions of personal responsibility), and self-reinforcement (i.e. infrequent self-reward and self-administering excessive punishment) (L.P. Rehm, personal communication, October 9, 2000). A sample SCQ item is, 'Criticizing myself is often the best way to help me get through a difficult task.'

Construct Validity

The strongest construct validity evidence for the SCQ derives from studies demonstrating an expected increase in SCQ scores after self-control therapy for depression (Rehm, 1984). Scores on the SCQ also predicted postpartum depression when administered during the second trimester of pregnancy (O'Hara et al., 1982). Discriminant validity is supported by significant correlations between the SCQ and Beck Depression Inventory of 0.16 (Rosenbaum, 1980) and 0.31 (O'Hara et al., 1982), indicating the SCQ is not a measure of depression per se. Rude (1989) investigated the constructs underlying the SCQ using exploratory factor analysis (EFA) and identified the following factors: (1) positive focus, (2) self-reward and long-range focus, (3) external locus of control, (4) external standards for self-appraisal, (5) self-punishment, and (6) fatalism (Rude, 1989). According to Rude, Factors 1 and 5 reflect self-reinforcement, Factor 2 reflects both self-reinforcement and self-monitoring, and Factor 4 reflects self-evaluation, indicating the three components of Kanfer's model are assessed by the SCQ. Factors 3 and 6 are not consistent with Kanfer's model.

Convergent Validity

A significant correlation between the SCQ and the Self-Control Schedule (SCS) of 0.42 (Rosenbaum, 1980) provides some support for convergent validity of the SCQ. As described earlier, the SCS is a more general measure of coping skills, including self-control related cognitions and behaviours.

Frequency of Self-Reinforcement Questionnaire (FSRQ)

The FSRQ (Heiby, 1982) consists of 30 items scored as 'true' or 'false'. The total score for the FSRQ ranges from 0 to 30. A cutoff score of 17 has been used to discriminate between high and low frequency of self-reinforcement (Heiby, 1982, 1983a, 1983b; Varese, Pelowski, Riedel & Heiby, 1998).

Reliability

The FSRQ has demonstrated high internal consistency (split-half reliability = 0.87) and high test–retest reliability over an 8-week interval ($r = 0.92$) (Heiby, 1983a). The stability of the FSRQ was also indicated by results demonstrating that the number of self-reinforcing statements made by individuals across situations correlate highly with FSRQ scores ($r = 0.72$ to 0.79). The number of statements across situations, however, did not differ significantly, suggesting the generalizability of self-reinforcement (Heiby, 1982).

Content Validity

The FSRQ was developed based on Rehm's (1977) definition of self-control, which incorporated Kanfer's model to explain depressive

symptomatology. Heiby (1982) referred to self-control as self-reinforcement and suggested that the three components of self-control are constituent elements of self-reinforcement. From an initial pool of 100 items generated by Heiby (1982), 10 judges selected those items that conformed to Rehm's definition of self-control, as well as those that were amenable to a 'true' or 'false' response format. To be retained, an item must have achieved 80% inter-judge agreement. This process yielded the 30-item FSRQ. A sample item is, 'I don't often think positive things about myself.'

Construct Validity

Construct validity of the FSRQ is supported by significant correlations with health locus of control, amount of exercise, exercise motivation, self-motivation (Heiby, Onorato & Sato, 1987), and life satisfaction (Seybolt & Wagner, 1997) as hypothesized. Predicted significant negative relationships were found between scores on the FSRQ and measures of anxiety (Heiby et al., 1987) and depressive symptomatology (Heiby, 1983b; Heiby et al., 1987; Schlatter, Heiby, Dubanoski, Kameoka & Denney, 1993; Dubanoski et al., 1996; Wilkinson, 1997; Varese et al., 1998; Wong, Heiby, Kameoka & Dubanoski, 1999). Discriminant validity has been demonstrated by non-significant correlations with social desirability (Heiby, 1982), gender (Parmar & Cernovsky, 1993; Seybolt & Wagner, 1997), and psychiatric diagnoses (Parmar & Cernovsky, 1993).

Support for construct validity also has been provided by findings of three experimental studies. First, in a crossover treatment study of four cases of depression, two cases that demonstrated deficient self-control skills, as assessed by the FSRQ, achieved clinically significant improvements following self-control therapy for depression (Heiby, 1986). Second, scores on the FSRQ were shown to increase significantly as a result of self-control therapy for depression (Heiby, Ozaki & Campos, 1984). Third, manipulation of environmentally controlled reinforcement showed that low scorers (<17) on the FSRQ experienced significantly greater depressed mood as a result of decreased experimenter-controlled reinforcement (Heiby, 1983b).

Wagner, Holden, and Jannarone (1988) conducted exploratory factor analyses of the FSRQ and found five factors underlying the measure: (1) self-evaluation, (2) self-reinforcement and self-reward, (3) don't self-praise, (4) be self-critical, and (5) responding emotionally to criticism and to self-evaluation. Wagner et al. noted that while the self-evaluative and self-reinforcement aspects of Kanfer's self-control model are adequately represented by FSRQ items, the self-monitoring aspect of self-control was not.

Convergent Validity

Convergent validity of the FSRQ has been demonstrated by significant positive correlations between FSRQ scores and reported self-praise on analogy tasks ($r = 0.69$) and on anagram tasks ($r = 0.65$) (Heiby, 1983a). In addition, the FSRQ is also significantly correlated with the frequency of daily self-monitored self-reinforcement ($r = 0.78$), as well as experimenter ratings of subjects' tendency to self-reinforce ($r = 0.42$) (Heiby, 1982).

The Self-Control Questionnaire (SCQ-Brandon)

The Self-Control Questionnaire developed by Brandon and his colleagues (1990) (SCQ-Brandon) is composed of 16 items rated on a 5-point scale. Total SCQ-Brandon scores range from 16 to 80. No norms or cutoff scores are available.

Reliability

Internal consistency reliability for the SCQ-Brandon is high, with a Cronbach's coefficient alpha of 0.80 (Brandon et al., 1990). Temporal stability of the measure has not been reported.

Content Validity

The SCQ-Brandon was designed to measure behavioural outcomes of self-control skills rather than self-control skills per se. A sample item is 'I snack between meals'. The SCQ-Brandon was developed to assess physical and emotional health-related behaviours. The authors defined self-control in terms of electing to engage in a low probability behaviour over a high probability behaviour (Brandon et al., 1990). This definition parallels Kanfer's criterion for achieving effective self-control skills, namely persistence in a low

probability target behaviour in opposition to competing higher probability behaviours, without supportive environmental reinforcement. Because the SCQ-Brandon measures outcomes of self-control rather than self-control as a construct, item content does not clearly reflect the three components of self-control (i.e. self-monitoring, self-evaluation, and self-reinforcement).

To establish content validity of the SCQ-Brandon, the author (Brandon et al., 1990) and his colleagues identified 10 health-related areas (e.g. eating behaviours, emotional control, exercise behaviour, study habits) in which behavioural outcomes of self-control could be assessed. Six to eight items were generated for each health-related area. Items were reviewed by six judges who were instructed to select behavioural outcome items that are highly dependent on self-control skills and items that most clearly indicate presence or absence of self-control skills. EFA of the SCQ-Brandon yielded the following five factors defined by 16 items: (1) eating behaviour, (2) time management, (3) emotional control, (4) social behaviour, and (5) financial planning (Brandon et al., 1990). These factors are consistent with 5 of the 6 rationally derived health-related areas assessed by the SCQ-Brandon.

Construct Validity

Because the SCQ-Brandon is designed to measure behavioural outcomes of self-control rather than self-control skills per se, construct validity of the SCQ-Brandon has been evaluated by inspecting the relation between scale scores and health behaviours. Brandon et al. (1990) found a significant correlation between scale scores and fitness level among cyclists ($r = 42$) and that these scores significantly distinguish between a group of cyclists who exercise regularly from a group of college students who do not.

Convergent Validity

Some support for the convergent validity of the SCQ-Brandon was provided by a significant moderate correlation ($r = 35$) with the California Personality Inventory (CPI) Self-Control subscale (Brandon et al., 1990). The CPI subscale, however, is a more general measure of self-control that was not developed based on Kanfer's definition of self-control.

The Lifestyle Approaches Inventory (LSA)

The LSA (Williams et al., 1992) is a 16-item instrument, scored on a 5-point scale. Total score on the LSA ranges from 0 to 64. No norms or cutoff scores are provided.

Reliability

Reliability estimates for the LSA is high with a reported Cronbach's coefficient alpha of 0.80 and test–retest reliability over a one-week interval of 0.90 (Williams et al., 1992).

Content Validity

The LSA was developed to measure self-control as well as various indicators of health, including self-efficacy and health habits (Williams et al., 1992). According to the authors, the LSA was also developed to complement cognitively oriented measures such as the SCS and SCQ, and the behaviourally oriented SCQ-Brandon.

Content validity of the LSA is derived from the text of a self-help book, *Manage Your Life* (Williams & Long, 1991), which summarizes 20 years of self-management research. An initial pool of 48 items drawn from this text by Williams et al. (1992) was reduced to 16 items based on the results of an EFA. Four factors resulted: (1) performance focus and efficiency, (2) goal directedness, (3) timelines of task accomplishment, and (4) organization of physical space. A sample item from factor 2 is, 'In most situations, I have a clear sense of what behaviours would be right or wrong for me.'

Construct Validity

Construct validity of the LSA is supported by significant positive correlations with self-efficacy, life satisfaction, purpose in life, physical health status and health habits, and significant negative correlations with external locus of control and perceived stress. Discriminant validity was demonstrated by non-significant relationships between the LSA and religious beliefs and practices (Williams et al., 1992). Further construct validity support was provided by the following findings: (1) as predicted by the authors, LSA scores were significantly more highly correlated with

scores on a general self-efficacy scale than scores on a social self-efficacy scale, and significantly higher mean scores were found among female, middle-aged, and educated subjects (Williams et al., 1992); (2) LSA scores were significantly negatively related to scores on the Judgement–Perception index of the Myers–Briggs Type Indicator ($r = -40$; Williams, Verble & Price, 1995), suggesting that self-management is related to an organized personality characteristic; and (3) consistent with the prediction that lower degree of self-management is associated with risk for problem-drinking behaviours, LSA scores were found to be significantly negatively correlated with scores on the Michigan Alcoholism Screening Test (McKee, 1996).

Convergent Validity

Convergent validity of the LSA was supported by significant and moderately high correlations with both the SCS ($r = 68$) and SCQ-Brandon ($r = 69$) (Williams et al., 1992). These findings are consistent with the authors' aim to develop an instrument that assessed both cognitive aspects of self-control, as measured by the SCS, and behavioural aspects of self-control, as measured by the SCQ-Brandon.

FUTURE PERSPECTIVES

The literature suggests that each of these self-control instruments can be further developed and validated. These suggestions include the following.

Construct validity evidence for the SCQ has focused on the measure's utility in studies on depression. It has been suggested that the SCQ may be an effective measure of vulnerability for depression (Rehm & Rokke, 1988; O'Hara et al., 1982); however, the SCQ may also be predictive of other psychopathologies.

According to Wagner and colleagues (1988), the FSRQ contains superfluous items that could be replaced by items that strengthen internal consistency of the measure and improve the assessment of self-monitoring skills. Also, replacing the 'true' or 'false' format of the FSRQ with a Likert scale format may improve the sensitivity of the instrument and make it more conducive to factorial investigation (Wagner et al., 1988). An advantage of the FSRQ, however, is that cutoff scores guide test interpretation.

The SCQ-Brandon requires further psychometric evaluations, particularly evidence for the measure's validity. For example, in support of the measure's construct validity, relationships between self-control skills and behavioural outcomes measured by the SCQ-Brandon need to be demonstrated.

Perhaps the most crucial need for the LSA is clearer articulation of the construct it purports to measure. The absence of a clear definition of lifestyle organization limits efforts to validate the LSA. Indeed, in light of the assessment literature reviewed here, consensus on the definition of 'self-control' (or self-regulation or self-management) is currently the most pressing requirement for the assessment of self-control skills.

CONCLUSIONS

Currently, there are at least four self-report instruments designed to assess self-control skills. These instruments vary along several dimensions. The SCQ and the FSRQ closely adhere to Kanfer's three-component model of self-control, while the SCQ-Brandon and the LSA are based on other theoretical models. Similarly, while item content of the SCQ and FSRQ was designed to measure components of self-control as defined by Kanfer, the SCQ-Brandon and the LSA, in part, were constructed to measure behavioural outcomes of self-control skills.

SELF-EFFICACY

INTRODUCTION

Perceived self-efficacy is concerned with people's beliefs in their capabilities to produce given attainments (Bandura, 1997). Perceived self-efficacy operates a core factor in the agentic causal structure of social cognitive theory (Bandura, 2001). This belief system is the foundation of human motivation and accomplishment. Unless people believe they can produce desired outcomes by their actions, they have little incentive to act, or to persevere in the face of difficulties. Whatever other factors serve as motivators, they are rooted in the core belief that one has the power to accomplish things by one's actions.

One cannot be all things, which would require mastery of every realm of human life. People differ in the areas in which they cultivate their efficacy and in the levels to which they develop it even within selected pursuits. Thus, the efficacy belief system is not a global trait but a differentiated set of self-beliefs linked to distinct realms of functioning. Multidomain measures reveal the patterning and degree of generality of people's sense of personal efficacy.

STRUCTURE OF SELF-EFFICACY BELIEFS

There is no all-purpose measure of perceived self-efficacy. The 'one-measure-fits-all' approach usually has limited explanatory and predictive value because most of the items in an all-purpose measure may have little or no relevance to the selected domain of functioning. Moreover, in an effort to serve all purposes, items in a global measure are usually cast in a general, decontextualized form leaving much ambiguity about exactly what is being measured and the level of task and situational demands that must be managed. Scales of perceived self-efficacy must be tailored to the particular domains of functioning that are the object of interest.

Although efficacy beliefs are multifaceted, social cognitive theory identifies several conditions under which there is some covariation even across distinct domains of functioning. Interdomain relations occur when different spheres of functioning are served by similar subskills; generic self-regulatory strategies are applied across different realms of activity; beliefs in one's learning efficacy are generalized across different types of challenges; there is co-development across dissimilar activity domains; and powerful mastery experiences produce a generalized transformational restructuring of efficacy beliefs.

CONTENT VALIDITY

The content of efficacy scales should accurately reflect the construct. Self-efficacy is concerned with perceived capability. The items should be phrased in terms of *can do* rather than *will do*. *Can* is a judgement of capability; *will* is a statement of intention. Perceived self-efficacy is a major determinant of intention, but the two constructs are conceptually and empirically separable. Perceived self-efficacy should also be distinguished from other constructs such as self-esteem, locus of control, and outcome expectancies. Perceived efficacy is a judgement of capability; self-esteem is a judgement of self-worth. Locus of control is concerned not with perceived capability, but with belief about whether outcomes are determined by one's actions or by forces outside one's control. High locus of control does not necessarily signify a sense of empowerment and well-being. For example, students may believe that high academic grades are entirely dependent on their performance (high locus of control), but feel despondent because they believe they lack the efficacy to produce those superior academic performances. Perceived self-efficacy should also be distinguished from outcome expectations which are judgements about the physical, social, or self-evaluative outcomes that are likely to flow from given performances.

FUNCTION OF SELF-EFFICACY BELIEFS

Perceived efficacy plays a key role in human functioning because it affects behaviour not only directly, but by its impact on other key determinants such as goals and aspirations, outcome expectations, affective proclivities, and perception of impediments and opportunities in the social environment (Bandura, 1986, 1995, 1997; Maddux, 1995; Schwarzer, 1992). Efficacy beliefs influence whether people think erratically or strategically, optimistically or pessimistically; what courses of action they choose to pursue; the challenges and goals they set for themselves and their commitment to them; how much effort they put forth in given endeavours; the outcomes they expect their efforts to produce; how long they persevere in the face of obstacles; their resilience to adversity; how much stress and depression they experience in coping with taxing environmental demands; and the accomplishments they realize.

Meta-analyses across different spheres of functioning confirm the influential role of perceived self-efficacy in human self-development, adaptation, and change (Holden, 1991; Holden, Moncher, Schinke & Barker, 1990; Multon, Brown & Lent, 1991; Stajkovic & Luthans, 1998).

DOMAIN SPECIFICATION AND SELF-EFFICACY MULTICAUSALITY

The construction of sound efficacy scales relies on an informative conceptual analysis of the factors governing the selected domain of functioning. Knowledge of the activity domain specifies which aspects of personal efficacy should be measured. Consider the self-management of weight as an example. Weight is determined by what people eat, by their level of exercise which burns calories and can raise the body's metabolism, and genetic factors that regulate metabolic processes. A comprehensive efficacy assessment would be linked to the contributing behavioural factors over which people can exercise some control. This would include perceived capability to manage food purchases, to exercise control over eating habits, and to adopt and stick to an increased level of physical activity. Perceived self-efficacy will account for more of the variation in weight management if the assessment includes perceived capability to regulate food purchases, eating habits and exercise than if it is confined solely to eating habits. If negative affect triggers overeating, assessment of perceived efficacy for affect regulation will explain additional variance in self-management of weight. Thus, multifaceted efficacy scales not only have predictive utility, but provide insights into the dynamics of self-management of behaviour.

If self-efficacy scales are targeted to factors that, in fact, have little or no impact on the domain of functioning, such research cannot yield a predictive relationship. If, for example, relaxation does not affect drug use, then perceived self-efficacy to relax will be unrelated to consumption of drugs because the causal theory is faulty. Under these circumstances, null results will reflect faulty theory rather than self-efficacy irrelevancy. In short, self-efficacy scales must be tailored to relevant activities and assess the multifaceted ways in which efficacy beliefs operate within the selected activity domain.

GRADATIONS OF CHALLENGE

Perceived efficacy should be measured against levels of task demands that represent gradations of challenges or impediments to successful performance. Self-efficacy appraisals reflect the level of difficulty individuals believe they can surmount. If there are no obstacles to overcome, the activity is easily performable and everyone has uniformly high self-efficacy for it.

The events over which personal influence is exercised can vary widely. It may entail regulating one's own motivation, thought processes, performance level, emotional states, or changing environmental conditions. The content domain should correspond to the area of functioning one seeks to manage. The nature of the challenges against which personal efficacy is judged will vary depending on the sphere of activity. Challenges may be graded in terms of level of ingenuity, exertion, accuracy, productivity, threat, or self-regulation required, just to mention a few dimensions of performance demands.

Many areas of functioning are primarily concerned with self-regulatory efficacy to guide and motivate oneself to get things done that one knows how to do. In such instances, self-regulation is the

capability of interest. The issue is not whether one can do the activities occasionally, but whether one has the efficacy to get oneself to do them regularly in the face of different types of dissuading conditions. For example, in the measurement of perceived self-efficacy to stick to a health-promoting exercise routine, individuals judge how well they can get themselves to exercise regularly under various impediments, such as when they are under pressure from work, are tired or depressed; in foul weather; or when they have other commitments or more interesting things to do.

Constructing scales to assess self-regulatory efficacy requires preliminary work to identify the forms the challenges and impediments take. People describe in open-ended interviews and pilot questionnaires the things that make it hard for them to perform the required activities regularly. The identified range of challenges or impediments are built into the efficacy items. Sufficient gradations of difficulties should be built into the efficacy items to avoid ceiling effects.

RESPONSE FORMAT

In the standard methodology for measuring efficacy beliefs, individuals are presented with items portraying different levels of task demands and rate the strength of their belief in their ability to execute the requisite activities. They record the strength of their efficacy beliefs on a 100-point scale, ranging in 10-unit intervals from 0 ('Cannot do'); through intermediate degrees of assurance, 50 ('Moderately certain can do'); to complete assurance, 100 ('Certain can do'). A simpler response format retains the same scale structure and descriptors but uses single unit intervals ranging from 0 to 10.

Scales that use only a few steps should be avoided because they are less sensitive and less reliable. Efficacy scales are unipolar, ranging from 0 to a maximum strength. They do not include negative numbers because a judgement of complete incapability (0) has no lower gradations.

Preliminary instructions should establish the appropriate judgemental set. People are asked to judge their operative capabilities as of now, not their potential capabilities or their expected future capabilities. It is easy for people to imagine themselves to be fully efficacious in some hypothetical future. However, in the case of perceived self-regulatory efficacy to maintain a given level of functioning over time, people judge their assurance that they can perform the activity regularly over designated periods of time. For example, recovered alcoholics would judge their perceived capability to refrain from drinking over specified time intervals.

Efficacy beliefs differ in generality, strength, and level. People may judge themselves efficacious across a wide range of activity domains or only in certain domains of functioning. In addition, efficacy beliefs vary in strength. Weak efficacy beliefs are easily negated by disconfirming experiences, whereas people who have a tenacious belief in their capabilities will persevere in their efforts despite innumerable difficulties and obstacles. Strength of perceived self-efficacy is not necessarily linearly related to choice behaviour. A certain threshold of self-assurance is needed to attempt a course of action, but higher strengths of self-efficacy will result in the same attempt. The stronger the sense of personal efficacy, however, the greater the perseverance and the higher the likelihood that the chosen activity will be performed successfully.

One can also designate self-efficacy beliefs in terms of level, i.e. the number of activities individuals judge themselves capable of performing above a selected cutoff value of efficacy strength. However, converting a continuous measure of efficacy strength into a dichotomous measure on the basis of a minimal cutoff strength value loses predictive information.

A more sensitive and informative measure is provided by computing the probability of successful performance as a function of the strength of perceived self-efficacy (Bandura, 1977). This microlevel analysis retains the predictive value of variations in strength of efficacy beliefs.

MINIMIZING RESPONSE BIASES

The standard procedure for measuring beliefs of personal efficacy includes a number of safeguards to minimize any potential motivational effects of self-assessment. Self-efficacy judgements are recorded privately without personal identification to reduce social evaluative concerns. People make multiple judgements of their efficacy across the full range of task demands within the activity domain. Perceived efficacy and behaviour are assessed in

different settings and by different assessors to remove any carryover of social influence from assessment of one factor to the other.

If merely recording a level of efficacy made it so, personal change would be trivially easy. People would rate themselves into grand accomplishments. Numerous tests for reactive effects of self-assessment have been conducted (Bandura, 1997). The findings show that people's level of motivation, affective reactions, and performance attainments are the same regardless of whether they do or do not make prior efficacy judgements. The non-reactivity of self-efficacy assessment is corroborated across cognitive, affective, and behavioural spheres of functioning. Making efficacy judgements does not increase congruence between perceived efficacy and behaviour under either high or low social demand for consistency. Nor are efficacy judgements influenced by a responding bias to appear socially desirable, regardless of whether the domain of activity involves sexual behaviour, alcohol consumption, smoking, dietary practice, or self-management of diabetes.

ASSESSMENT OF PERCEIVED COLLECTIVE EFFICACY

The theorizing and research on human agency has centred almost exclusively on personal influence exercised individually. People do not live their lives autonomously. Many of the outcomes they seek are achievable only through interdependent efforts. Hence, they have to work together to secure what they cannot accomplish on their own. Social cognitive theory extends the conception of human agency to collective agency. People's shared beliefs in their collective power to produce desired results is a key ingredient of collective agency.

A group's attainments are the product not only of shared knowledge and skills of the different members, but also of the interactive, coordinative, and synergistic dynamics of their transactions. Therefore, perceived collective efficacy is not simply the sum of the efficacy beliefs of individual members. Rather, it is an emergent group-level property. A group operates through the behaviour of its members. It is people acting coordinately on a shared belief, not a disembodied group mind that is doing the cognizing, aspiring, motivating, and regulating. There is no emergent entity that operates independently of the beliefs and actions of the individuals who make up a social system.

There are two main approaches to the measurement of a group's perceived efficacy. The first method aggregates the individual members' appraisals of their personal capabilities to execute the particular functions they perform in the group. The second method aggregates members' appraisals of their group's capability operating as a whole. The latter holistic appraisal encompasses the coordinative and interactive aspects operating within groups.

Some researchers advocate that perceived collective efficacy be measured by having a group arrive at a single judgement of the group's capability (Guzzo, Yost, Campbell & Shea, 1993). The discussion approach is methodologically problematic, however. Constructing unanimity about a group's efficacy via group discussion is subject to the distorting vagaries of social persuasion by members who command power and other types of pressures for social conformity (Earley, 1999). Persuasory efforts to reach consensus can alter members' views. Moreover, no social system is monolith with a unitary sense of efficacy. A forced consensus to a single judgement masks the variability in efficacy beliefs among the various factions within a social system and misrepresents their beliefs.

The two informative indices of perceived collective efficacy differ in the relative weight given to individual factors and interactive ones, but they are not as distinct as they might appear. Being socially situated, and usually interdependently so, individuals' judgements of their personal efficacy are not detached from the other members' enabling or impeding activities. Rather, a judgement of individual efficacy inevitably embodies the coordinative and interactive group dynamics. Conversely, in judging the efficacy of their team, members certainly consider how well key teammates can execute their roles.

Given the interdependent nature of the appraisal process, linking efficacy measured at the individual level to performance at the group level does not necessarily represent a cross-level relation. The two indices of collective efficacy are at least moderately correlated and predictive of group performance. It is commonly assumed that an emergent property is operative if differences between groups remain after statistical methods are used to control variation in characteristics of

individuals within the groups. The analytic logic is fine, but the results of such statistical controls can be quite misleading. Because judgements of personal efficacy take into consideration the unique dynamics of a group, individual-level controls can inadvertently remove most of the emergent group properties.

The relative predictiveness of the two indices of collective efficacy will depend largely on the degree of interdependent effort needed to achieve desired results. The aggregated holistic index is most suitable for performance outcomes achievable only by adept teamwork. Under low system interdependence, members may inspire, motivate, and support each other, but the group outcome is the sum of the attainments produced individually rather than by the members working together. Aggregated personal efficacies are well suited to measure perceived efficacy for the latter types of endeavours.

A growing body of research attests to the impact of perceived collective efficacy on group functioning (Bandura, 2000). Some of these studies have assessed the motivational and behavioural effects of perceived collective efficacy using experimental manipulations to instil differential levels of perceived efficacy. Other investigations have examined the effects of naturally developed beliefs of collective efficacy. The latter studies have analysed diverse social systems, including educational systems, business organizations, athletic teams, combat teams, urban neighbourhoods, and political systems.

The findings taken as a whole show that the higher the perceived collective efficacy, the higher the groups' motivational investment in their undertakings, the stronger their staying power in the face of impediments and setbacks, the more robust their resilience to adversity, and the greater their performance accomplishments.

FUTURE PERSPECTIVES

There are several directions in which the assessment of perceived self-efficacy will evolve. Complex performances are governed by multiple forms of perceived efficacy involving self-management of cognitive, motivational, affective, and behavioural aspects of functioning operating in concert. With advances in knowledge of multicausality, assessments of multifaceted efficacy contributors to human functioning will supplant simple single faceted efficacy causation. Further developments in the methodology of self-efficacy assessment will broaden and extend this line of inquiry to perceived self-efficacy to regulate one's affective life as well as performance accomplishments.

Social cognitive theory distinguishes among three different forms of agency – they include production of effects through *direct individual agency*; through *proxy agency* relying on the efforts of intermediaries; and by *collective agency*. Each of these expressions of agency is rooted in the belief that one can make things happen. Much of the research on perceived self-efficacy has focused on individual efficacy and the processes through which it exerts its effects. In many activities, people do not have direct control over social conditions and institutional practices that affect their lives. They seek their well-being and security through proxy agency. In this socially mediated exercise of perceived efficacy, people try to get those who have the resources and expertise or who wield influence and power to act on their behalf to get the outcomes they desire. There is much conceptual and methodological work to be done on the largely neglected phenomenon of the exercise of proxy agency through perceived efficacy.

The extraordinary advances in electronic technologies and growing globalization of human interconnectedness present new adaptational challenges and enlarged opportunities for people to exercise some measure of control over their personal development and to shape their national life. These rapidly evolving realities place a premium on perceived collective efficacy. Here, the efficacy locus is the perceived capabilities of social subsystems, such as families, communities, educational systems, business organizations, and the perceived efficacy of social and political institutions to make a difference in people's lives. The development of valid measures of perceived collective efficacy for these various subsystems is another future direction of research that has promise of providing new insights into the determinants, structure, and function of collective efficacy in people's efforts to shape their social future.

The management of everyday life requires a blend of individual, proxy, and collective agency. These different forms of human agency are rooted in a sense of personal efficacy. Indeed, beliefs of personal efficacy to manage one's life circumstances and to have a hand in effecting societal changes contribute substantially to perceived collective

efficacy (Fernández-Ballesteros, Díez-Nicolos, Caprara, Barbaranelli & Bandura, 2001). Research into the relationship among these different forms of perceived efficacy and how they operate in concert is important to a broad understanding of human self-development, adaptation and change.

CONCLUSIONS

Scientific advances are greatly accelerated by methodological development of assessment tools for key determinants of human functioning. Quality of assessment provides the necessary basis for stringent empirical tests of theory. Given the centrality of efficacy beliefs in people's lives, sound assessment of this factor is crucial to understanding and predicting human behaviour and guiding personal and social change.

SELF-OBSERVATION (SELF-MONITORING)

INTRODUCTION

Self-monitoring refers to an assessment procedure in which individuals systematically observe instances of their own behaviour and maintain records of those occurrences. In self-monitoring, more than in other forms of assessment, the client becomes the assessor, learning to observe, document and measure behaviour as well as environmental variables that may control it. The

resultant data ideally reflects the frequency, duration or intensity of target behaviours in the client's everyday environment, and provides a baseline against which to measure the effects of therapeutic interventions. In addition to measuring target behaviour, self-monitoring is often used to identify situational variables and consequences associated with the client's behaviour in natural settings. This information can be used in a functional analysis of problem behaviours and the development of therapeutic interventions. In the following sections, the advantages and disadvantages of self-monitoring relative to other assessment methods are discussed. Issues concerning the implementation and accuracy of self-monitoring as well as its therapeutic effects are also described. Some potential directions for future research are also offered.

SELF-MONITORING AS AN ASSESSMENT TOOL

Self-monitoring is widely used in clinical practice (Elliot, Miltenberger, Kaster-Bundgaard & Lumley, 1996), and is considered to be one of the most direct forms of behavioural assessment (Cone, 1978). It is more direct than self-report questionnaires in that it assesses behaviours at the time of their occurrence. It is therefore less reliant on processes of recollection and less susceptible to memory errors and distortions. The main disadvantages of self-monitoring relative to self-report is that self-monitoring requires more time and effort, and that there are no population norms for self-monitored data.

Self-monitoring also has advantages over the use of direct observation by trained observers. Direct observation is often impractical, due to time constraints, cost factors, the scarcity of adequately trained observers, and the likelihood that the presence of observers will alter the frequency or form of target behaviours. Moreover, many treatment targets are not amenable to direct observation. For example, thoughts and feelings are private by nature and cannot be observed by others. Alternatively, behaviours may be private by convention, such as sexual behaviour, and the less intrusive method of self-monitoring may be more appropriate.

METHODS OF SELF-MONITORING IN BEHAVIOURAL ASSESSMENT

The general goals of behavioural assessment are to measure behaviour and identify its controlling variables. This investigative process typically begins with a broad focus on a wide range of potential target behaviours, and progressively focuses on more specific behavioural targets for change. Self-monitoring methods can be selected to suit each stage of this process.

Diary Formats

In early stages of clinical assessment, specific behaviours to target for change may be difficult to identify. For example, the goal of anger management can include a wide range of behaviours that may or may not be problematic for a given client. Even when target behaviours are readily identified, it is important to collect as much information as possible concerning the settings and consequences associated with these behaviours. Under these circumstances, a diary format may be most useful. Diary formats allow the self-recorder to supply more elaborate and narrative descriptions of their behaviour and the environment in which it occurs. As specific target behaviours are identified, the format of self-monitoring can become more structured, assessing specific targets while minimizing the extent of recording required.

Frequency Counts

Ideally, self-recordings would be made each time a specific target behaviour occurs. This facilitates identifying variations in behaviour across time and situations and provides detailed baseline data. A continuous frequency count is most feasible when a target behaviour is discrete and fairly low in frequency, with a short duration. Less discrete responses such as anxiety can be difficult to discriminate as separate instances. Recording all occurrences of highly frequent behaviours can be too burdensome. Alternatives include other methods of self-monitoring, or recording frequency counts for only a portion of the day.

Duration Recording

In some cases, the amount of time consumed by a target behaviour is of more interest than its

frequency. For instance, if the client's goal is to increase positive interactions with a spouse, the length of each interaction will vary and would be important to observe and record. Duration recordings may also be desirable for target behaviours that are repetitive and very frequent such as nail-biting or obsessional ruminations.

Time Sampling

Time sampling can be used as an alternative to duration recordings or when frequency counts of highly frequent behaviours would be impractical. In time sampling, long intervals such as a day are divided into smaller time blocks of time. The client records whether or not the target behaviour occurred within each of these smaller intervals. Clients might also be provided with a variable cue and asked to 'spot check' whether or not a target behaviour is occurring at the time of the cue. These time sampling procedures yield less precision than frequency counts or duration recording but can be less demanding of self-recorders.

Self-Ratings

In clinical settings, the intensity of a target behaviour is frequently important (e.g. urges to use drugs or self-cut). When this is the case, self-ratings may be incorporated into self-monitoring. Using this method, the clinician provides the self-monitor with a scale to be used in rating more subjective dimensions of self-observed behaviour. For example, Linehan (1993) employs diary cards in Dialectical Behaviour Therapy that include a 5-point scale to assess urges to self-harm. Self-rating scales are highly flexible and can be used to assess problems for which questionnaires are unavailable.

PROMOTING ACCURATE DATA COLLECTION

The primary concern in assessment is that measurements of behaviour reflect the actual frequency and setting of the client's behaviour. When utilizing self-monitoring, the clinician is concerned with promoting compliance with the procedure and accurate data collection. While compliance is necessary for accurate data collection, it is not a sufficient condition for accuracy. In the following subsections, strategies for promoting compliance and accuracy are discussed separately.

Compliance

Several steps may be taken proactively to promote compliance with self-monitoring procedures. These include: (1) providing explicit instructions and a clear rationale for self-monitoring (Shelton & Ackerman, 1974); (2) providing reinforcement for data collection; (3) making the importance of self-monitored data explicit for the client by discussing self-monitored data throughout treatment; (4) asking self-monitors to enter into contracts to collect data; (5) collecting monetary deposits from self-monitors, to be returned after data collection; and (6) collecting data between sessions via daily mailings to the therapist (Harmon, Nelson & Hayes, 1980) or through random phone checks made by therapists (Christensen, Johnson, Phillips & Glasgow, 1980).

When problems with compliance occur, several hypotheses might be explored. Non-compliance may reflect more general behavioural patterns or difficulties in the therapeutic relationship (Baird & Nelson-Gray, 1999). Non-compliance might more specifically reflect that the client does not see the relevance or importance of self-monitoring. Exploring problems with compliance might also reveal skill deficits of the client, as well as environmental factors and cognitions that interfere with compliance (Shelton & Levy, 1981).

Accuracy

It has been suggested that self-observers have a unique capacity for accuracy because they alone are able to potentially observe all occurrences of their target behaviours (Kazdin, 1974a). Of course, an absolute criterion for the accuracy of an assessment device cannot be determined, given that there are no error free measures of behaviour. The relative accuracy of self-monitoring has typically been assessed by comparison to data obtained by independent direct observers or collected via mechanical devices. Self-monitored data may also be compared to behavioural by-products. For instance, self-monitored caloric intake might be compared to weight changes (Mahoney, Moura & Wade, 1973).

In the 1970s and early 1980s, considerable research was devoted to identifying variables that enhance or detract from the accuracy of self-monitored data. Accuracy can be compromised by disruptions either in the act of self-observation or that of self-recording. Difficulties with self-observation can result when the client is unsure what the target behaviours are, or when targets are 'fleeting', habitual, or insidious, and thus difficult to notice.

Other factors may interfere with the act of recording. Recordings may be neglected if the self-recording procedure is too cumbersome or complex. Alternatively, expectancies about the potential approval or criticism of a therapist may cause socially undesirable behaviours to be under-recorded or desirable behaviours to be over-recorded. When ongoing data collection has not occurred, data sheets may be filled in just prior to treatment sessions and bear little relation to the client's actual experience over the week.

Several procedures have been shown to enhance the accuracy of self-monitored data. These include: (a) clearly defining target behaviours; (b) providing training to self-monitors (Mahoney, 1977; Nelson, Lipinski & Boykin, 1978); and (c) emphasizing the importance of accurate data collection and providing reinforcement for accurate data collection (Lipinski, Black, Nelson & Ciminero, 1975). Accuracy can also be enhanced by (d) minimizing the number of target behaviours being monitored at one time (Hayes & Cavior, 1977); (e) requiring that recordings be made immediately after the target behaviour occurs (Frederiksen, Epstein & Kosevsky, 1975); and (f) regularly checking the accuracy of self-monitored data and informing self-recorders of these accuracy checks (Lipinski et al., 1975; Lipinski & Nelson, 1974; Santogrossi, 1974).

THERAPEUTIC EFFECTS OF SELF-MONITORING

Reactivity

In assessing behaviour, it is frequently a concern that the method of measurement can alter the form or frequency of behaviours being assessed. This phenomenon is termed *reactivity*. Research devoted to reactivity in self-monitoring has produced consistent observations that implementing self-monitoring procedures alters the frequency of behaviours being measured. While this creates problems in obtaining a valid baseline, the effect is often advantageous for clients, because reactive effects of self-monitoring consistently occur in the therapeutic direction. That is, unwanted behaviours tend to decrease and desirable behaviours tend to increase when they are self-monitored (Sieck & McFall, 1976). The change is typically small and short-lived but represents some relief for clients at the beginning stages of treatment and may encourage continued investment in therapy.

Several factors can enhance or attenuate reactive effects of self-monitoring. Existing evidence suggests that reactivity can be enhanced when the target behaviour is clearly defined and overt (Hayes & Cavior, 1977), when the self-monitor is motivated to change (Lipinski et al., 1975), when goals for behaviour change are clearly specified (Kazdin, 1974b), when reinforcement for that change is provided by clinicians (Lipinski et al., 1975), when each occurrence of the target is self-recorded (Frederiksen et al., 1975), and when concurrent response requirements are limited (Hayes & Cavior, 1977). Some studies have also indicated that more intrusive recording devices enhance reactive effects (Kirby, Fowler & Baer, 1991; Nelson et al., 1978) although null findings have also been reported (Nelson, Hay, Devany & Koslow-Green, 1980; Schloss, Thompson, Gajar & Schloss, 1985). Finally, for undesirable behaviours, reactive effects have been increased by requiring that recordings be made just prior to the occurrence of the target behaviour (Bellack, Rozensky & Schwartz, 1974; Rozensky, 1974).

FUTURE PERSPECTIVES

Self-monitoring enjoys widespread use among clinicians. It is also an integral part of ongoing data collection within several empirically validated psychological treatments. Despite its widespread acceptance within clinical settings, research in the area of self-monitoring has declined steadily since the late 1970s (Korotitsch, Gaynor & Nelson-Gray, 1998). This appears to correspond with a dramatic proliferation of brief self-report questionnaires

and research addressing the psychometric properties of those instruments. The decline in research is ironic and troubling given the aforementioned popularity of self-monitoring within clinical settings. Several lines of potential research have been suggested. For instance, little information is available regarding potential differences in accuracy as a function of diagnostic status. The relative accuracy and sensitivity of self-monitoring as compared to other types of measurement such as interviews or self-report questionnaires is also unclear. The impact of self-monitoring on clients might also be examined in an attempt to ascertain if self-monitoring procedures might in some situations have detrimental effects. Finally, and most critically, there has been little attention toward empirically evaluating the utility of self-monitored data within treatment. The impact of collecting and using self-monitored data, on the effectiveness of treatment, has not been adequately evaluated.

CONCLUSIONS

Self-monitoring is a widely used method of behavioural assessment in which clients are asked to observe and to document occurrences of behaviours that are being targeted in their treatment. The popularity of self-monitoring among clinicians can be attributed to its flexibility and directness. Self-monitoring procedures can be tailored or modified to accommodate individual clients with highly specific or idiosyncratic behavioural targets. Self-monitoring also provides a more direct measurement of behaviours in the client's everyday environment because recordings are made at the time the target behaviour occurs rather than reported at a later time.

Self-monitoring research has generally focused on the relative accuracy and reactivity of self-monitoring procedures. Early research has offered specific suggestions for implementing self-monitoring in such a way as to maximize the accuracy of data collection, as well as the reactive effects that are therapeutically desirable. While the research devoted to this area has declined since the 1980s, self-monitoring remains a standard form of assessment within clinical settings. The selection of a particular self-monitoring procedure should be guided by consideration of its appropriateness for a particular target behaviour, and by practical concern for the convenience of clients. The procedures should be thoroughly explained and clearly related to the overall goals of treatment. When implemented in this manner, self-monitoring can provide a detailed ongoing account of behaviour that can be useful at all stages of assessment and treatment.

SELF-PRESENTATION MEASUREMENT

INTRODUCTION

Self-presentation is the generic term for the human tendency to describe oneself in a self-serving fashion. Because this tendency is assumed to interfere with accurate psychological assessment, much work has been put into devising methods to measure and control for self-presentation. For reviews, see Paulhus (1991) and the entry on Self-Report Distortions' in this volume.

Assessment psychologists would prefer to eliminate or, at least, identify sources of variance that are irrelevant to the attributes being measured (e.g. traits, values, attitudes). Self-presentation is usually assumed to fall in this irrelevant category. Sometimes it is – for example, when a random subset of job applicants is so motivated to land the job that they are faking good. When self-presentation is stable across time and assessment context, however, self-presentation tendencies are called response styles. Because consistent styles must have their own cognitive and/or motivational roots, they can be studied as personality traits in their own right. And their manifestations of self-presentation are likely to go

well beyond biased behaviour on self-report instruments.

In this entry, three types of such styles are distinguished and substantiated with popular examples. The first type comprises trait measures of self-aware tendencies to engage in self-presentation (e.g. Self-Monitoring Scale). The second category comprises measures that diagnose the overall social desirability of current responding (e.g. the Impression Management scale). The third category comprises self-deceptive biases in self-descriptions (e.g. the Narcissistic Personality Inventory).

TYPE 1: SELF-AWARE PREDICTORS OF TRAIT SELF-PRESENTATION

This type refers to measures where respondents accurately report their tendencies toward self-presentation. The classic example is Snyder's (1974) construct of self-monitoring. Although it began with a conception closely linked to the clinical definition (see the entry on 'Self-Observation' in this volume), Snyder's construct is now quite distinct. In the most recent elaboration, self-monitoring is described as the active construction of public selves designed to achieve social ends; that is, favourable outcomes (Gangestad & Snyder, 2000).

The instrument designed to assess the construct – Snyder's (1974) Self-Monitoring Scale – has been immensely popular. Median reliabilities are 0.71 (alpha) and 0.73 (2-week test–retest). One repeated criticism concerned the multidimensionality of the original 25 item SMS (e.g. Briggs & Cheek, 1988) and even of the reduced 18-item version (Romera, Luengo, Garra & Otero-Lopez, 1994).

Nonetheless, the SMS has proved especially useful as a pre-test before laboratory studies of self-presentation. For example, it has been shown to predict who will manipulate their self-decriptions to get a date (Rowatt, Cunningham & Druen, 1998). Critics have replied that the bulk of its successful predictions derive from its major component, extraversion (John, Cheek & Klohnen, 1996).

A more complex instrument in this category is the Social Skills Inventory (e.g. Riggio, Watring & Throckmorton, 1993). Respondents are asked about a wide variety of social skills such as empathy, and perspective taking. Again, extraversion appears to be a significant underlying component of this measure.

TYPE 2: DIAGNOSTIC INDICATORS OF IMPRESSION MANAGEMENT

This second type of measure indexes the total amount of positivity in an individual's self-descriptions. One example is the Impression Management (IM) scale (Paulhus, 1991). Typical reliabilities are 0.80, for internal consistency, and 0.76 for 4 month test–retest reliability. The Marlowe–Crowne scale and various lie-scales also fall into this category.

These measures are often used to diagnose desirability response sets: that is, the degree to which respondents have engaged in impression management while completing a battery of self-report measures. Temporary distortion can arise from any number of sources; for example, high motivation among some applicants or patients to appear positive to an interviewer. Trait contributions include the tendency to avoid negative self-presentations (Paulhus, 1991).

Unfortunate for the simple self-presentation interpretation is that some high scorers are accurately reporting that they have desirable traits, in particular traits such as agreeableness, and responsibility (McCrae & Costa, 1983). Interpretation of the scores as a desirability response set can certainly be ruled out if the self-report conditions entail no demand for self-presentation; for example, anonymous administration.

An unassailable usage for type 2 measures is for indexing situational differences in demand for self-presentation: since mean levels are being compared, no interpretation of individual differences is involved.

TYPE 3: SELF-DECEPTIVE SELF-ENHANCEMENT

Some individuals seem to believe their own exaggerated self-descriptions. Presumably, this tendency requires a degree of self-deception to ignore or distort information that would undermine a biased self-view (Paulhus, 1986). The classic example is the narcissistic personality who continually enhances the self and derogates others because of a belief that he/she is superior to

others (e.g. Morf & Rhodewalt, in press; Paulhus, 1998). A solid body of evidence on so-called 'normal narcissists' has demonstrated that their self-descriptions are exaggerated even when the administration is anonymous. The most popular measure of this type is the Narcissistic Personality Inventory (Raskin & Hall, 1981). Typical reliabilities are 0.78 for internal consistency and 0.74 for a 2-month test–retest reliability. Another such measure is the Self-Deceptive Enhancement scale (Paulhus, 1991).

COMPARISONS AND RECOMMENDATIONS

Each category of measures reviewed here involves a different linkage between a self-presentation style and a tendency to engage in self-presentation. High scores on Type 1 and Type 3 measures identify individuals who possess the type of character prone to self-presentation (e.g. self-monitors and narcissists). Such measures allow prediction of who will self-enhance in the future: (1) Type 3 chronically self-enhances and (2) Type 1 enhances when opportune. In contrast, Type 2 measures indicate who is currently giving desirable answers.

Consider a study where the SMS (Type 1), the IM scale (Type 2), and the NPI (Type 3) are administered twice – the second time under a demand for positive self-presentation. Scores on the SMS and NPI should change very little and can be used to predict relative degrees of self-enhancement behaviour at time 1 or time 2. But, because scores on the SMS or NPI are not responsive to situational demand, they cannot be used to indicate the absolute level of self-presentation. In contrast, Type 2 measures such as the IM scale will be higher at time 2 because they measure absolute levels of self-presentation: their interpretation at time 1 should be in terms of valid personality differences.

The different styles of self-presentation tapped by measures of Types 1 and 3 is reflected in the flexibility of their self-presentation. A situational deterrent such as accountability will alter the self-presentation behaviour of self-monitors but not that of narcissists. Attempts to embarrass or confront the latter do not seem to have any effect (Robins & John, 1997): narcissist self-enhancement cannot be bridled.

CONCLUSIONS

Self-presentation is among the most complex of human behaviours. Accordingly, the analysis and diagnosis of self-presentation as a style is a challenging problem to assessment psychologists. The above analysis suggests guidelines but is surely not the final word.

More work is required to compare the three categories of self-presentation styles head-to-head across a variety of circumstances. One new but already active issue concerns differences in self-presentational style across the type of content that is being self-presented. Paulhus and John (1998) have argued that the content of self-presentation styles involves the two primary human values of agency and communion. So far, available measures in this category emphasize self-enhancement that is agentic; that is, emphasizing competence and energy. Yet to be developed is a corresponding measure of moralistic or communal self-enhancement.

SELF-REPORT DISTORTIONS (INCLUDING FAKING, LYING, MALINGERING, SOCIAL DESIRABILITY)

INTRODUCTION

Self-report inventories are among the most commonly used methods of psychological assessment. Their validity depends largely on the cooperation of test-takers, who are generally instructed to read items carefully and provide honest responses. When test-takers provide inaccurate information, the results of the inventory may be invalid. Several types of response distortion, also known as response sets, response biases, or test-taking attitudes, have been recognized, and many multiscale inventories of personality and psychopathology include one or more validity scales designed to detect them. The accuracy of these validity scales in identifying response distortions has been widely studied. This entry reviews types of response distortions and methods for their detection.

TYPES OF RESPONSE DISTORTION

Negative impression management, also described as overreporting of symptoms, malingering, or faking bad, is a deliberate attempt to create an impression of disturbance or impairment by exaggerating or fabricating problems and negative characteristics. Positive impression management, also described as underreporting of symptoms, defensiveness, socially desirable responding, or faking good, is a deliberate attempt to create a favourable impression by falsely denying problems and endorsing positive characteristics. Random responding, in which the test-taker responds independently of the content of the items, can result from poor reading or language skills, lack of cooperation, carelessness, poor concentration, or confusion. Acquiescence and naysaying are tendencies to respond indiscriminately in the 'true' or 'false' directions, respectively, without consideration of item content. Because any of these response distortions can invalidate the results of a self-report inventory, standard clinical practice generally requires consideration of scores on validity scales before proceeding with interpretation of test results (Greene, 2000). Table 1 lists instruments and scales commonly used to detect response distortions.

Table 1. Selected instruments and scales used to detect response distortions

Response distortion	Instrument	Scale(s)
Negative impression management	MMPI-2	F, Fb, Fp
	PAI	NIM
	SIMS	Li, Af, N, P, Am
	SIRS	RS, SC, IA, BL, SU, SEV, SEL, RO
Positive impression management	MMPI-2	L, K, S
	PAI	PIM
	PDS	IM, SDE
Random responding	MMPI-2	VRIN, F
	PAI	ICN, INF
Acquiescence/naysaying	MMPI-2	TRIN

Note. For Instrument: MMPI-2 = Minnesota Multiphasic Personality Inventory – Revised, PAI = Personality Assessment Inventory, SIMS = Structured Inventory of Malingered Symptoms, SIRS = Structured Interview of Reported Symptoms, PDS = Paulhus Deception Scales. For Scales: F = Infrequency, Fb = Back Page Infrequency, Fp = Infrequency-Psychopathology, NIM = Negative Impression Management, Li = Low Intelligence, Af = Affective Disorders, N = Neurological Impairment, P = Psychosis, Am = Amnesia, RS = Rare Symptoms, SC = Symptom Combinations, IA = Improbable or Absurd Symptoms, BL = Blatant Symptoms, SU = Subtle Symptoms, SEV = Severity of Symptoms, SEL = Selectivity of Symptoms, RO = Reported vs. Observed Symptoms, L = Lie Scale, K = Correction Scale, S = Superlative Scale, PIM = Positive Impression Management, IM = Impression Management, SDE = Self-Deceptive Enhancement, VRIN = Variable Response Inconsistency, ICN = Inconsistency, INF = Infrequency, TRIN = True Response Inconsistency.

The current mental health and legal systems include several circumstances in which important consequences depend on the outcome of psychological testing (Baer, Wetter & Berry, 1992; Berry, Baer & Harris, 1991). Plaintiffs suing for psychological damages may receive large financial settlements if their psychological injuries are judged to be significant. Work-related injuries may lead to pensions through Workers' Compensation, while disabilities related to military service may result in eligibility for pensions through the Social Security system. Criminal defendants may wish to be found unfit to stand trial or not guilty by reason of insanity. These situations can present test-takers with powerful incentives to exaggerate or fabricate psychological problems. Other situations provide incentives for positive impression management. For example, divorcing parents undergoing court-ordered psychological examinations to resolve custody disputes, applicants for jobs or training programmes for which psychological testing is required, and patients wishing to be released from treatment, or transferred to less restrictive units or institutions, may attempt to create an unrealistically favourable impression. As psychologists are increasingly asked to evaluate individuals in these situations, the availability of tools for detecting response distortions has assumed increased importance.

PREVALENCE OF RESPONSE DISTORTIONS

Scales designed to detect response distortion are less accurate in populations with very low base rates of distortion (Finn & Kamphuis, 1995). For this reason, assessment of response distortion in individual cases should consider the base rate of distortion in the population of interest. In research settings, where results of inventories have no important consequences for test-takers, who often remain anonymous, base rates of response distortion are probably very low. In forensic settings, where individuals are being evaluated for competency to stand trial, criminal responsibility, or mental state at the time of the crime, estimates of the base rate of malingering have ranged from 31–47% (Berry et al., in press). In personnel selection and child custody evaluation settings, Baer and Miller (2002) found a median base rate estimate of positive impression management of 30%. These findings suggest that in settings where the results of psychological testing have important consequences for the client, the possibility of impression management should routinely be considered (Berry, Wetter & Baer, 1995). Base rates of random responding have rarely been investigated. In samples of students, community members, and police

recruits completing the MMPI-2, Berry et al. (1992) found that 29–60% of participants acknowledged providing some random responses. However, the reported number of items answered randomly was low, ranging from 12 to 38 items.

DETECTION OF NEGATIVE IMPRESSION MANAGEMENT

Overreporting of symptoms has been the most widely studied of the response distortions, largely because of the increased acceptance of psychological assessment methods within the legal system. Most scales designed to detect overreporting on self-report inventories consist of items that appear to have pathological or deviant content, but that are rarely endorsed in normative or psychiatric samples. For example, the F (Infrequency) Scale of the MMPI-2 (Butcher et al., 1989) consists of items endorsed by less than 10% of the inventory's original normative sample, with content including paranoid thinking, antisocial attitudes, hostility, and poor health (Graham, 2000). The Infrequency-Psychopathology (Fp) Scale of the MMPI-2 (Arbisi & Ben-Porath, 1995) and the Negative Impression Management Scale of the Personality Assessment Inventory (PAI: Morey, 1991) both consist of items with pathological or bizarre content that are rarely endorsed by either normal or psychiatric samples. Respondents attempting to create a negative impression have been found to endorse many more of these items than are endorsed by individuals with psychiatric impairments.

Several factors can complicate the detection of malingering (Berry, Wetter & Baer, 1995). For example, respondents might accurately describe some of their symptoms, while exaggerating others and entirely fabricating still others. The specificity of the malingerer's complaints also must be considered. Some respondents may endorse most items that appear pathological (global malingering), while others may attempt to endorse only symptoms of a specific disorder. Global malingerers may be easier to detect than those feigning specific disorders (Graham, 2000). A related issue is coaching, or the extent to which test-takers have obtained information designed to help them complete psychological tests in a manner consistent with their goals. Many attorneys believe that educating their clients about the psychological tests they will complete, including informing them of the nature of validity scales, is their professional responsibility (Wetter & Corrigan, 1995). Thus, it seems likely that some test-takers involved in legal proceedings have been coached by their attorneys in how to complete the tests. Studies suggest that malingerers who have been coached about the purpose and function of validity scales are more difficult to detect than those who have not been coached, or who have been coached about symptoms of a specific disorder (Graham, 2000).

Empirical studies and meta-analytic reviews of the literature have suggested that several overreporting scales are at least moderately effective in discriminating overreporters from honest responders. The overreporting scales of the MMPI and MMPI-2 have obtained the most empirical support. In a meta-analytic review of studies comparing malingering and honest groups on the original MMPI, Berry et al. (1991) found a mean effect size (*d*) of 2.07 for several overreporting scales, suggesting that malingering and honest respondents differ by just over two standard deviations on these scales. Optimal cutting scores were variable, as were correct classification rates, although many were respectable. Rogers, Sewell, and Salekin (1994) obtained similar results in a meta-analysis of overreporting scales on the MMPI-2. In addition, several tests dedicated exclusively to the detection of malingering have shown promising efficacy, including the Structured Inventory of Malingered Symptoms (SIMS: Smith & Burger, 1997), and the Structured Inventory of Reported Symptoms (SIRS: Rogers, Bagby & Dickens, 1992).

DETECTION OF POSITIVE IMPRESSION MANAGEMENT

Most scales designed to detect underreporting of symptoms or socially desirable responding include items of one or two types. Some describe common minor faults or weaknesses that most individuals are willing to acknowledge, whereas others describe rare virtues that few honest respondents would claim. Both types of items have low endorsement frequencies in clinical and non-clinical populations. Thus, respondents who consistently deny common problems and endorse

rare virtues are judged to be responding defensively. This approach is exemplified by the Lie (L) Scale of the MMPI-2, and the Positive Impression Management (PIM) Scale of the PAI. An alternative approach is illustrated by the K (Correction) Scale of the MMPI-2, which was empirically derived by identifying items that discriminated a non-clinical sample from patients with known psychopathology who had produced MMPI profiles with no clinical elevations. Similarly, the Superlative (S) scale of the MMPI-2 was empirically derived by comparing a group of pilots seeking employment with a major airline with the MMPI-2 normative sample.

The detection of positive impression management also can be complicated by several factors. Studies of coaching suggest that test-takers who have been informed of the presence and purpose of validity scales often can produce profiles that appear normal without elevating the relevant validity scales (Baer & Sekirnjak, 1997). Some authors have suggested that socially desirable responding in certain circumstances, such as personnel selection and child custody evaluation, should be considered normal, as most test-takers in these settings are 'putting their best foot forward' rather than denying significant problems (Bathurst, Gottfried & Gottfried, 1997). Careful assessment is required to discriminate normally functioning test-takers who are responding defensively due to situational demands from test-takers who are concealing psychopathology. Other authors have suggested that socially desirable responding reflects substantive variance in personality, and that the ability to respond in a socially desirable manner when applying for a job predicts emotional stability and conscientiousness (Ones, Viswesvaran & Reiss). Finally, Paulhus (1998) has suggested a two-factor model of socially desirable responding, in which impression management is a deliberate attempt to create a positive impression, while self-deceptive enhancement is an unconscious overconfidence similar to narcissism. The Paulhus Deception Scales (1998) assess both factors.

Empirical studies and meta-analytic reviews of the literature have suggested that positive impression management is more difficult to detect than negative impression management, perhaps because participants in most studies of positive impression management are students, job applicants, or custody litigants, many of whom are probably functioning within normal limits. Differences between their scores when responding honestly and when making the best possible impression may be small, especially when compared to differences between their scores when responding honestly and when making a bad impression. A meta-analytic review of studies comparing fake-good and honest groups on the original MMPI (Baer et al., 1992) found a mean effect size (d) of 1.05 across several scales, suggesting that honest and fake-good respondents differ by just over one standard deviation on these scales. Optimal cutting scores were variable, as were correct classification rates, which ranged from 48% to 84%. Baer and Miller (2001), in a similar review of studies using the MMPI-2, found a mean effect size (d) of 1.26. Correct classification rates were similar to those reported by Baer et al. (1992) and were generally lower when participants feigning good adjustment had been coached about validity scales.

DETECTION OF RANDOM RESPONDING, ACQUIESCENCE, AND NAYSAYING

Scales used to detect random responding typically consist of pairs of items with either similar or opposite content, so that the test-taker's response to one item can be predicted from the response to the other item. Pairs with similar content should be answered similarly (both true or both false) whereas pairs with opposite content should be answered differently (one true and one false). For each pair that is answered inconsistently, a point is added to the random responding scale. This approach is exemplified by the Variable Response Inconsistency (VRIN) Scale of the MMPI-2 and the Inconsistency (ICN) Scale of the PAI. Random responding can also be detected with Infrequency scales (described earlier), as random responders are likely to endorse a number of these items by chance. However, Infrequency scales alone cannot distinguish between random responding and overreporting. For this reason, use of an inconsistency scale such as VRIN to clarify an elevation on an Infrequency scale is often recommended (Graham, 2000).

Few scales designed to detect acquiescence and naysaying have been developed. The best known is probably the True Response Inconsistency (TRIN) Scale of the MMPI-2. The TRIN scale

consists of pairs of items with opposite content. Responding inconsistently by indiscriminately giving primarily true or primarily false responses elevates the TRIN scale.

The efficacy of inconsistency scales in detecting random responding, acquiescence, and naysaying has been investigated in very few studies. Berry et al. (1991) found high classification rates for the VRIN scale in a study of random responding on the MMPI-2 in a college student population. Research investigating the efficacy of the TRIN scale for detecting acquiescence and naysaying is needed.

FUTURE PERSPECTIVES

Research on detection of response distortions is likely to improve as research designs are refined. The simulation design, in which participants instructed to fake are compared to participants given the standard instructions, is the most commonly used. Its ecological validity can be improved in several ways (Rogers, 1997). Participants instructed to fake should be similar to those with whom the test is used in clinical practice. The comparison group given standard instructions should be carefully chosen. For example, in overreporting research, participants instructed to feign psychopathology should be compared to individuals with true psychiatric problems, while studies of positive impression management should compare normally functioning individuals with those who have significant problems but are instructed to attempt to conceal them. Participants instructed to feign good or bad adjustment should be given a realistic scenario to imagine in which feigning might occur, such as, 'Imagine you are applying for a desirable job.' They should be instructed to respond believably in their feigned presentation, and should be offered incentives for successful feigning. Their understanding of and compliance with their feigning instructions should be assessed.

Alternative research designs with greater ecological validity should be used more frequently. The differential prevalence design compares groups of participants whose circumstances provide incentives for feigning with participants who appear to have no such motives. For example, anonymous volunteers might be compared to a sample of custody litigants or criminal defendants being evaluated for fitness to stand trial. The known groups design compares individuals known to have responded honestly with those known to have distorted their responses. Unfortunately, the latter group is difficult to identify, and may not be representative of feigners who are never caught. However, converging evidence across these different methodologies may greatly increase confidence in the utility of validity scales (Rogers, 1997).

CONCLUSIONS

In some settings, response distortions may be sufficiently common that their presence should routinely be evaluated. As no method of identifying response distortions is perfectly accurate, the consequences of both false positive and false negative errors should be carefully considered. Because false accusations of feigning may be extremely detrimental to test-takers, determinations of feigning should only be made on the basis of converging evidence across several methods, including self-report inventories, behavioural observations, interviews, and collateral sources of information. At the same time, failure to rule out feigning in a setting where it may be suspected could be a disservice to the test-taker. Thus, in settings where response distortion is likely, its assessment should not be ignored, but must be conducted with great care. Continued research on improving methods for detecting response distortion is essential.

SELF-REPORT QUESTIONNAIRES

INTRODUCTION

Self-report questionnaires are among the most widely used methods of psychological measurement. This popularity is a result of many advantages that self-reports hold over alternative assessment methods. Most notably, the technique is very time-efficient for the researcher or professional; time spent on administration and scoring is typically minimal, yet a large amount of information can be obtained. Furthermore, the technique lends itself to high quality standardization. With objective scoring procedures, responses can be compared with high reliability to various large samples of interest, a normative comparison facilitated by the efficiency of the data collection. Finally, self-report offers an opportunity to directly measure the phenomenology or subjective experience of the respondent. For most constructs, subjective experience is

a critical part of the concept; it is difficult to imagine how someone could be given psychological descriptors such as 'unhappy' or 'obsessive' without a glimpse into their personal experience. Self-report provides an objective, standardized method for capturing these experiences (in contrast to unstructured approaches such as interviews or free associations), while less direct assessment techniques (such as projective, observational, or psychophysiological methods) can at best only allow inferences about phenomenology. Thus, self-report holds a vital place in the assessment of virtually any construct in personality and psychopathology.

However, there have also been concerns expressed over the accuracy of self-reported information as an indication of psychological status. One source of distortion may arise from efforts to deceive the recipient of the information; for example, examinees may attempt to appear either better adjusted or more poorly adjusted than is actually the case. A second source may arise from limited insight or self-deception; examinees may genuinely believe that they are doing quite well or quite poorly, but this belief might be at odds with the impression of objective observers. A third source of distortion can also arise from carelessness, confusion, or indifference in taking a test; examinees who answer questions with little reflection (or even randomly) may yield results that do not accurately mirror their experiences. Because of these threats to validity of self-reported information, a number of procedures and strategies (discussed elsewhere in this volume) for identifying such distortion and understanding its effects have been developed.

CONCEPTUAL APPROACHES TO QUESTIONNAIRE CONSTRUCTION

Rational/Theoretical Approach

The oldest approach to questionnaire construction is the rational/theoretical approach, in which a developer attempts to design an instrument that reflects a particular theory about a concept. This theoretical reflection can either be implicit or explicit. The items of the Woodworth Personal Data Sheet, an early psychiatric screening, represented Woodworth's implicit theory about important indicators of psychological adjustment. The items of the Myers–Briggs Type Indicator represent an attempt to implement an explicit psychological theory of personality, that of C.G. Jung.

An important advantage of the rational approach to personality test construction is that it places an important emphasis upon the *content validity* of the resultant measure. However, the early rational approach also suffered from a failure to use data-driven procedures in the development of the measures. Thus, these measures were entirely dependent upon the assumptions of the test author, and erroneous assumptions could take place at the level of interpreting the theory, or at the level of generating the relevant indicators. For example, a test author might assume two concepts are related when they are not, or create an item that may turn out to be measuring something other than what was intended.

Empirical Approach

In the *empirical* approach, only the correlates of item responses matter; the content or theoretical applicability of the item is of no interest in construction. Meehl (1945) provided a manifesto for this approach, stating 'it is suggested tentatively that the relative uselessness of most structured personality tests is due more to a priori item construction than to the fact of their being structured' (p. 6). The empirical approach to test construction is exemplified by the construction of the MMPI and the Strong Vocational Interest Blank. In these instruments, a single extra-test criterion – ability to differentiate members of a criterion group from those in a control group – was used to select items for the final version of these tests. For the Strong, group membership involved persons engaged in particular occupations, while for the MMPI, group membership was determined by psychiatric diagnosis.

The potential advantages of the approach over the rational method were numerous. These tests were unlikely to fall subject to the mistaken theoretical assumptions of the test authors since the approach was explicitly atheoretical. The approach was initially thought to be less susceptible to attempts at impression management; the strategy resulted in the inclusion of a number of so-called 'subtle' items on scales, and these items had content with little apparent relationship to

the construct for which it was scored. Unfortunately, the promise of the empirical approach was often not borne out by subsequent research. First, it quickly became apparent that empirical tests were not free from distortions introduced by efforts at impression management. A second shortcoming was items selected to make one particular discrimination had problems when called upon to make other discriminations. For example, MMPI items, selected to contrast normality with psychopathology, tended to have difficulty making distinctions among different forms of psychopathology. Finally, reliance upon empirical methods to identify 'subtle' items appeared to lead to the inclusion of such items on scales that appeared to have questionable validity upon cross-validation.

Statistical Approach

The *statistical* or *classic psychometric* approach shares a quantitative emphasis with the empirical perspective, but was based upon the classical approach to psychometric theory and also influenced by the development of factor analysis. Rather than external criterion group membership as in the empirical approach, the statistical approach emphasized item intercorrelations as its basis for test construction. This approach seeks to construct scales that are collections of homogeneous indicators of an underlying factor, and they typically will demonstrate high internal consistency (i.e. high KR-20/coefficient alpha).

Such instruments have often selected items by focusing upon item–scale correlations, and choosing those items that demonstrated the largest correlations with the parent scale. Another related strategy involves the factor analysis of item intercorrelations, with factor loadings serving as the basis for item selection. Such factor analyses can be either exploratory or confirmatory, but are typically conducted to evaluate the hypothesis that the item set is unidimensional. This approach also results in scales demonstrating high internal consistency, but there is an added potential to identify problems in discriminant validity, as other factors may emerge and certain items may display multiple high loadings, suggesting ambiguity in interpretation of the item. However, an overemphasis upon item intercorrelation in test construction can lead to the 'attenuation paradox' (Loevinger, 1957) whereby increasing internal consistency through the inclusion of redundant (hence highly correlated) items will decrease validity for measurement of complex constructs. Overemphasis on item intercorrelation can also impair the ability of a scale to capture depth as well as breadth in content validity, as factor analysis can segregate items reflecting a unidimensional construct onto different factors, as a function of differing item difficulties.

One of the most enduring examples of this approach to questionnaire construction is the Sixteen Personality Factor Questionnaire (Cattell, Cattell & Cattell, 1993). The basis of the instrument was Cattell's 'lexical' approach, which sought to identify source traits that explained individual differences as captured by personality adjective terms in the English language. Based upon factor analyses of personality data (including behavioural descriptions as well as questionnaire data), Cattell initially concluded that 16 obliquely related source traits formed the basis for most observable personality differences, and constructed a questionnaire to measure these source traits directly. Subsequent investigations have generally found that the 16 scales are not factorially independent, and efforts to replicate Cattell's results tend to find fewer factors than 16. One of the most popular models of normal personality in contemporary research, the 'five-factor model', resembles the higher order factors of Cattell's theory. The five factors include Neuroticism (worry/insecurity vs. calm/self-satisfied), Extroversion (sociable/affectionate vs. sober/reserved), Openness (imaginative/independent vs. conforming/orderly), Agreeableness (trusting/helpful vs. suspicious/exploitative), and Conscientiousness (organized/disciplined vs. careless/weak-willed). The utility and robust nature of the five-factor model has been supported in a number of research studies, and these five characteristics appear to persist throughout much of adult life. There are a number of instruments available for measuring these five dimensions, with one of the most popular being the NEO Personality Inventory (Costa & McCrae, 1992).

Construct Validation Approach

Construct validity represents the extent to which a test reflects a theoretical construct. Within this

framework, test development cannot proceed without a specification and elaboration of the construct to be measured. Cronbach and Meehl (1955) suggested that assigning variability in behaviour to a hypothetical construct requires a theory comprised of an interconnected system of laws (a 'nomological network') relating hypothetical constructs to one another and to observable behaviour. Thus, questionnaire development from this perspective involves the elaboration and refinement of potential indicators in this network (Loevinger, 1957; Jackson, 1971). Examples of instruments that have been developed from the construct validation perspective are the Personality Research Form (Jackson, 1967) and the Personality Assessment Inventory (Morey, 1991).

The construct validation process often involves three stages. The stage of *theory formulation* involves an explication of the content domain of the construct, including a consideration of *breadth* as well as *depth* of the construct. The *breadth* of content coverage refers to the diversity of elements subsumed within a construct, while *depth* refers to sampling across the full range of intensity or severity of a particular element of a construct. Also required at this stage is a delineation of the nature of the classification of constructs and the linkages between constructs in the model, and a specification of the relationship of constructs to external variables, such as aetiology or intervention. The second stage of *internal validation* involves the operationalization of the constructs and examining various internal properties of the classification; specific properties to be emphasized would depend on the theory elaborated in the initial stage. These properties might include interrater reliability, coverage of the classification, stability of measurement over occasions, internal correlation matrices, internal consistency of features assumed to be indicators of the same construct, characteristics of the item or test information curves, or the replicability of factorial structures across different samples. The third stage of construct validation involves *external validation*. At this stage, links of the constructs to other variables related to aetiology, course, or prediction must be tested. This process involves both convergent and discriminant validation (Campbell & Fiske, 1959). That is, in addition to showing that expected relationships prevail between the construct and to conceptually similar constructs, the process must also involve efforts to demonstrate that observed relationships are not attributable to constructs presumed not to be operating within the theoretical network (i.e. discriminant validity). There are a variety of threats to validity where discriminability plays a vital role. In addition to failures of a questionnaire to provide adequate discrimination among constructs, the influence of *response sets* and *response styles* and the operation of *test bias* (discussed elsewhere in this encyclopedia) can also be considered as issues of discriminant validity.

STRUCTURAL APPROACHES TO QUESTIONNAIRE CONSTRUCTION

Items in personality and psychopathology scales typically involve two aspects: a stimulus aspect (for example, the verbal presentation of a statement or question) and a response method (for example, describing the above item as either 'true' or 'false') that is generally constrained to facilitate scoring.

Stimulus Properties of Items

While the nature of questionnaire items will vary across types of measures, it is helpful to keep several guidelines in mind. Items should be written simply and unambiguously, so that the content is directly relevant to the construct measured by the test. Good items should capture the experiences of the person manifesting the construct rather than those of an outside observer, such as a clinician. Because discriminant validity is often difficult to achieve, items should capture aspects that tend to be fairly unique or specific to the construct. Also, items should not reflect only the most extreme manifestations of the trait. If one assumes that there is meaningful dimensional variability on the construct, then it is important to have items that make discriminations at various points on this dimension. Items should also not be offensive or potentially biased with respect to any gender, ethnic, economic, religious, or other group, and colloquialisms or slang should be avoided to avoid problems in translation or cross-cultural application.

Response Properties of Items

There are a number of methods for scaling responses to items or combinations of items. The *binary summative* method involves a scale score that represents the total number of items endorsed in the direction of the construct; each item is thus scored '1' if so endorsed, and '0' if not endorsed in the critical direction. This method is simple to score, and in the case of binary response options, it is also easy for the respondent to understand. The primary disadvantage is that a limited amount of construct variance is captured by each item; thus, to achieve adequate scale reliability, it is typically necessary to include several items for each construct. The *binary weighted* item scaling method involves the use of items that are initially scored in a binary fashion, and then weighted according to some scaling scheme according to their supposed importance for the construct. In contrast to the binary summative method, it is assumed that all items are *not* comparable indicators; some are assumed to be more important than others, and thus are assigned greater weight in determining the final scale score. However, experimenter-assigned weights typically make little difference in the final result, and greater complexity in scoring and potential scorer reliability problems may offset any presumed gain in validity.

Guttman scaling relies upon items having a monotonic, deterministic pattern; any individual who endorses a particular item on a scale should also endorse items 'lower' on the scale. The scale is 'monotonic' in that this determinism works in only one direction; one does not know how a respondent will answer any items 'higher' on the scale. However, it is very difficult to assemble items that fit the model, and items can also fit that almost certainly do not form a unidimensional scale, simply by varying the base rate (i.e. the a priori probability) of endorsing particular items. *Thurstone scaling* attempts to place individuals along such a fixed continuum by identifying the scale 'values' of a number of different items, and placing respondents on that continuum according to where agreement with a particular attitude is expressed. This type of scaling is non-monotonic, in that a respondent would be expected to disagree with items 'above' his or her absolute placement on the scale, as well as disagree with items 'below' this placement. Again, it is typically difficult to find items that fit the scale model, as this pattern of endorsement probabilities is often seen only if items are 'doublebarrelled' to cut off individuals higher and lower on a continuum. Also, finding items that fit the model toward the extremes of the scale can be particularly difficult. *Rasch scaling* (*Item Response Theory*) models are based upon the item characteristic curve (ICC) that relates probability of endorsement to absolute scale placement of the respondent. The Rasch approach models the ICC with one parameter (the difficulty parameter), while two- and three-parameter models (incorporating discrimination and chance/guessing characteristics of items) are also used. In this approach, items may be scaled by examining the *item information function*, and individuals are scaled according to the information contained in the patterns of items endorsed.

Likert scaling involves the use of 5-point anchored response choices for a particular item, although 'Likert scales' have come to signify nearly any type of items with non-binary, graded response alternatives. Unlike the binary weighted scaling approach, Likert scales use item weights that reflect the respondent's behaviour. As such, the Likert approach often improves the reliability of a scale by capturing more respondent variability per item, particularly with scales comprised of relatively few items. Reliability increases as a function of number of scale steps, rapidly up to roughly 7 response alternatives, and begins to asymptote at about 11 alternatives. Because overuse of a scale midpoint may constitute a response style that could decrease scale reliability, use of an even number of alternatives may be preferable.

The *forced choice* technique requires selecting between response alternatives that differ in their relationship to the measured construct, but are equated with respect to some 'nuisance variable', such as social desirability. The effectiveness of this approach is controversial, with a number of potential shortcomings described. First, the social desirability of a response may be strongly tied to the context of evaluation and the use of universal ratings to equate items is unlikely to work across different contexts. The format also potentially loses information about the absolute strength of the characteristic, and for many

personality or psychopathological characteristics, social desirability is not merely a nuisance variable, but represents a valid aspect of the construct. In some respects, the forced choice technique is similar to a *rank-order method*, where respondents rank a series of items or statements according to some characteristic, such as personal preference. Rank order techniques are primarily interpretable as *ipsative* measures, meaning that they are most informative in making comparisons within an individual rather than across individuals.

CONCLUSIONS

Self-reports provide an efficient and reliable measure of the critically important subjective experience of the respondent. Although self-report is subject to various sources of distortion, the approach often includes some of the most sophisticated techniques for identifying and interpreting this distortion. There are numerous approaches to constructing self-report questionnaires, and these differences can be reflected in the conceptual underpinnings as well as in the structural format of the instrument. Although there is no single 'best' way to construct a questionnaire, the process is generally best guided by a well-articulated theory of the construct to be measured that specifies hypotheses about relevant indicators and relationships to other constructs.

SELF-REPORTS (GENERAL)

INTRODUCTION

The self-report is a method for collecting data whose source is the subject's verbal message about him/herself. The self-report as an assessment method is supported not only by methodological standards but also by knowledge derived from basic psychology research in the fields of language, memory, learning and neuropsychology.

Self-reports provide information about thousands of events, from subjects' external and observable conditions (what subjects do, their circumstances, etc.) to his/her internal events (what they think or feel, their plans, opinions, attributions, desires, etc.). These types of events can refer to the past, to the present, or even to subjects' expectations about the future.

Self-reports are the most widely used methods in psychological assessment in all applied fields (clinical, health, educational, work & organizational, etc.), as well as being useful within all theoretical perspectives (behavioural, cognitive, phenomenological psychoanalytical, psychometric, constructivist, systemic). Therefore, self-reports can be taken and studied from several theoretical, practical, analytical and structural perspectives (for a review see Fernández-Ballesteros, 2002; Meyer et al., 2001).

In psychological assessment the self-report method is considered as an essential form of data-collection for three basic reasons: (1) due to the *relative accuracy* of the information provided by the subject about him/herself and about public events, and for its *efficiency* (compared to other methods) in relation to its cost and benefits; (2) as the *preferred method* in the assessment of subjective and private events (Hollon & Bemis, 1981); and (3) due to its empirically demonstrated *value* in the description, diagnosis and prediction of human behaviour (Schwartz, Park, Knauper & Sudman, 1998).

Although self-reports are considered to be acceptable methods for collecting data, it is well known that they have important sources of errors or response distortions, such as social desirability, faking, impression management, acquiescence, etc., which should be investigated and controlled (see: 'Self-Report Distortions' and 'Self-Presentation Measurement').

The consideration of the self-report in scientific psychology has evolved in accordance with the epistemological assumptions of different theoretical frameworks, and has constituted a central element in the mentalism–physicalism and functionalism–structuralism debates. Historically, it has been the central method in the study of conscientiousness (Wundt, 1902), the object of critical review from behavioural epistemology (Watson, 1920), rejected by the first and second generations of behaviourists (Zuriff, 1985), the object of reconceptualization by the third generation (Mischel, 1968; Staats & Fernández-Ballesteros, 1987), and also a fundamental instrument, both in the study of personality variables and constructs (Wiggins, 1973), and in that of a wide variety of psychosocial characteristics from psychopathological conditions to risk factors, from work performance to environmental attitudes, so that it is considered indispensable throughout the long process of evaluation and change (for a review, see Schwartz, Park, Knauper & Sudman, 1998; Fernández-Ballesteros, 2002).

All self-reports involve questions and answers (oral or written), so that, depending on the structure of these questions and answers, self-reports have several *formats* – interviews, questionnaires, scales, self-monitoring, think-aloud protocols and other specific instruments – for recording subjects' verbal messages about themselves. Nevertheless, in the literature, self-reports are commonly reduced to those that present a structured and standardized format in questions and answers, such as questionnaires, inventories and self-rating scales.

In sum, the self-report is a commonly used method of data collection in psychology and other social sciences, which can be used to collect a broad range of psychological content and events that require different types of cognitive operations by subjects, which can be used differently by assessors from different theoretical perspectives, and which have several types of format. This entry will be dealing with these very general issues related to self-reports.

NATURE OF THE CONTENT REPORTED

As a data-collection method, self-reports have the peculiarity of facilitating the recording of data on a wide range of behavioural content: subjective and overt behaviours, and external events to the subject. Given that the medium of self-reports is thinking and language, they require a neurobiological substratum and a series of extremely complex neurocognitive operations. For these reasons, self-reports constitute a wide methodological category about which it is difficult to make a general appraisal. In order to approach such an appraisal, we will first need to make a brief analysis of the content about which subjects can provide information, and, second, about the cognitive operations the subject must carry out in the act of self-reporting, since these operations lead to specific biases in self-reports.

Hersen and Bellack (1977) pointed out that self-reports primarily collect information about what the subject does, thinks or feels, as well as subjective considerations about what he/she does, thinks and

feels. Moreover, human beings can report on external events and the relationships between external events and behaviour that occurred in the past and are occurring in the present, and about their elaboration upon them, as well as their predictions and expectations for the future.

From a methodological perspective, a general trait emerges from this assortment of events: the possibility of verifying them. The independent verifiability of a reported event is an important condition when we are to judge its validity or accuracy. In sum, self-reported content presents different degrees of *verifiability*. Thus, if people are asked about something they are *doing* at that time, given that this is a *public event*, the information is verifiable through observation. If people are asked about an observable situation in the past (for example, if their parents beat them as a child, or whether they had a particular illness), the chances of verifying such data becomes more complicated, and is sometimes impossible. Nevertheless, such information could be verified if we had archive data or reliable records from the time when it occurred. In other words, any event is verifiable insofar as it is observable and objective data on it are available – as occurs with reports on physiological events.

Finally, subjects can report cognitive *internal events* or their experience and/or elaborated thoughts about any observable fact or event for which as yet no verification is possible (the final criterion should be the subject him/herself (Cone, 1978).

In sum, we are faced with an apparent incongruence; that is, self-reports of verifiable events facilitate the validation process, while self-reports about non-verifiable events – for which we do not have other assessment methods – provide us with less reliable information.

Operations Required

It has already been stated that language is a human communication medium that requires neurobiological equipment (which has been shaped over throughout the individual's and species' development process) and a series of internal neurocognitive operations. Thus, in order to produce a verbal report on oneself, the subject must process the question, search for the required information in his/her memory and, finally, give a response that, in turn, must fit the format presented by the assessor.

There is important evidence from information processing psychology that identifies the conditions affecting the accuracy of self-reports as behavioural data, namely the *accessibility* of that information and the *time* to which it refers.

From a memory model, Ericsson and Simon (1980) stress that 'self-report X need not be used to infer that X is true, but only that the subject was able to say X' (p. 7). In other words, by 'accessibility' we understand the extent to which a reported event is known or can be known by the reporter. Therefore, a first condition of any self-reported event is its accessibility to the subject. For example if the subject is asked about how many times he/she braked when driving to the office this morning, he/she is unable to answer the question because such behaviour is automatic. When this type of question is asked, the subject is likely to answer with the 'available heuristic' (Tversky & Khaneman, 1973) or with the most probable or truthful response (Meichenbaum & Buttler, 1979). In other words, self-reports usually require complicated transformations of stored primary information because they can refer not only to facts but also to inferences about facts. For example, 'I go to religious services' is a stored fact, but any question regarding new inferences ('do you think that going to religious services is. . .') about this fact require, to some extent, cognitive transformations of the fact already stored. As Nisbett and Wilson (1977) point out, subjects may be accurate in reporting facts, but they are not accurate when they have to talk about interpretations of those facts.

Moreover, the complex web of operations required of subjects when they have to respond to a self-report is further complicated by a *time factor* – the event about which information is required may be in the past, the present or even the future. Memory principles should be applied in trying to understand the process of recovering the information stored at different times, or the processes involved when subjects have to predict their own behaviours or other events in the future (Ericsson & Simon, 1980; Nisbett & Wilson, 1977).

Sometimes, questions are asked about what subjects *usually* do. In these cases, subjects must retrieve information about a set of events stored from the relatively distant past and make decisions about the generality of those events: are they 'usual', 'frequent', 'rare' during that past period of time? Self-report distortions function in these complex operations, leading to important biases

related to individual differences in self-presentation (see: 'Self-Presentation Measurement' and 'Self-Report Distortions').

Finally, self-reports not only have to retrieve specific information: they must also transform the retrieved event-information to fit the response format (list of responses, rating scales, etc.). Thus, once again, response tendencies affect the accuracy of responses with regard to the original 'facts'.

Thus, knowledge from the psychology of language, of memory and of learning is extraordinarily relevant for optimizing the accuracy of self-report information as scientific data. Self-reports differ insofar as the required information is easily accessible (codified in the same format as it is demanded) or needs transformation. Furthermore, self-reports differ in terms of whether they relate to present events (for example, in the case of self-observation or self-register), they refer to past events, or they require the subject to make an 'average' over a long period of time. The greater the elaboration of the codified event the subject is required to make, the greater the possibility of distortion.

INFERENCES ABOUT SELF-REPORTS

Verbal messages – whatever their content – can be used in two essentially different ways: (a) Verbal messages about a particular event (e.g. 'I'm afraid') can be taken in an 'isomorphic' way – that is, what is reported is occurring or has occurred (the reporter actually is afraid), and the verbal statement substitutes the event; (b) Social scientists – including psychologists – tend to consider self-reports not as a way of assessing specific events, but as a set of verbal behaviours from which to infer other psychologically relevant concepts (e.g. from the reported 'being afraid', to infer that the person has a problem of 'anxiety'). Thus, after mathematical manipulations a set of verbal responses from self-reports collected and analysed by using inter-subject designs can be considered as signs of a given psychological construct which, in turn, serves to predict (as its correlate) other relevant human behaviours (e.g. from the information that a person feels 'depressed', we can infer that s/he may commit suicide).

Trait theories, based on correlational approaches, have given rise to hundreds of self-reports that assess dimensions or factors of personality: in all of them, the reported information is used at a very high level of inference; in other words, the verbal messages are considered as phenotypic expressions of an underlying genotypic characteristic in the subject. Throughout the history of psychology there has been intense debate between behavioural psychologists and personality psychologists over the value of self-reports taken as behavioural data or as signs of the existence of underlying psychological characteristics (Mischel, 1968).

This is not the place to enter more deeply into this important issue (see Sundberg, Tyler & Taplin, 1973). It is important to underline, however, that self-reports present different forms of validation insofar as they are used from different theoretical perspectives with different levels of inference.

TYPES OF SELF-REPORT

We have already referred to the fact that the particular format of a self-report depends on the way the questions are formed and how the responses are elicited. Naturally, in any *interview* self-reports are required (that is, reports by subjects about themselves), in a quite unstructured way (see entry on 'Interview (General)'). Similarly, *self-observation* or *self-monitoring* can be considered as variants of the self-report, generally concurrent with the to-be-assessed event itself, but there is no standard format (see 'Self-Observation (Self-Monitoring))'. Nevertheless, both the interview and self-observation are considered as methods independent of self-reports. Self-reports as such are those with a format in which the questions and answers are previously structured.

Questions

The questions used for collecting information generally present the event about which information is required. These questions, stimuli or items vary not only according to the content we referred to above, but also on the basis of a series of characteristics among which some of the most important are the verbal tense used and the specificity of the situational and response format.

Zuriff (1985) called self-reports 'messages in the first person', and it is true that a large proportion of self-report responses are formulated in the first person singular ('I'm upset', 'I'm sad'). However,

this is not always the case, since other types of formulation are also common – for example, the second person singular ('Do you sometimes want hustle and bustle?') or the first person plural ('We're a very close-knit group'), or even, with the object of masking the 'examination' situation, the third person (singular or plural), so that self-reports can refer to what the subject says a third person (to whom the item refers) does, thinks or feels.

Linguists have stressed the importance of the verbal tense used when collecting information through self-reports, insofar as it affects the subject's degree of involvement, and therefore influences responses. Assessors should take note of basic research in this area before making decisions about the use of verbal tense in self-reports.

With regard to the *situational and response generality–specificity* of questions, variation is wide, and depends on the theoretical approach from which they have been constructed. In the trait approach, questions tend to be quite non-specific ('I feel nervous'), while behavioural self-report items tend to present situational and response specificity ('In social situations my heart races'). These differences are related to the differences between formats assessing 'states' or 'traits' (e.g. Spielberger, 1972).

These aspects affect the degree of precision with which stimuli elicit information on situations, events, etc., and they therefore determine the extent to which information on the reported event must be processed. Reports with greater specificity maximize the precision of what is reported, and correspondence between the self-report and the reported fact is therefore higher. In contrast, general self-reports – which tend to require more transformation of the reported fact – involve more interference by the so-called response set. In sum, when the aim of the self-report is to collect behavioural data, the greater the specificity, the greater the precision, while ambiguous and/or general descriptions tend to be preferable when personality characteristics are to be assessed and the involvement of the response set is maximized.

Responses

Variation in types of response alternatives is an important factor, and even forms the basis of the three most frequent types of self-report: *Questionnaires*, *Inventories* and *Scales* (the term *inventory* is sometimes used interchangeably with *questionnaire*). The difference between these three instruments lies in the fact that the response alternatives in questionnaires tend to have the dichotomic format Yes/No (e.g. 'I find it very hard to ask for favors'...Yes/No), inventories tend to present a list of formalized response alternatives (e.g. 'How do you like to spend your time? (a) going to an art gallery; (b) visiting a museum; (c) going to a library') and, finally, rating-scales involve giving scores on a scale (of 3, 4, or more response alternatives), whose levels may use adjectives ('I like going to the cinema': 1 = A lot, 2 = Quite a lot, 3 = Not much, 4 = Not at all) or adverbial constructions referring to frequency ('frequently', 'usually', etc.). Another variant, also with multiple response alternatives, requires the ranking of a series of items by means of ipsative scores (e.g. ranking list of professions: 1st, 2nd, 3rd, etc.) (see Fernández-Ballesteros, 1992, 2002).

The formulation of stimuli and the selection of response alternatives are important in that they can lead to bias; subjects may respond to the item not according to its content, but rather according to the response alternatives offered. Thus, for example, self-report items differ in terms of their greater or lesser *social desirability* – in the extent to which the behavioural description they involve can be considered socially acceptable or unacceptable, and this can affect the subject's response. As regards dichotomic alternatives, they exercise their influence given that there appears to exist a tendency for *agreement* or for *negation*. Finally, scalar responses are affected by the tendency in some subjects to respond on the mid-point of the scale (*central tendency*), or at one pole or the other (see also entry on 'Self-Report Distortions').

FUTURE PERSPECTIVES AND CONCLUSIONS

Self-reports provide useful information, in some cases difficult to obtain through other procedures. Various reviews have stressed that the self-report is – together with the interview – the most commonly used method in psychological assessment, and that with the widest spectrum in terms of data-collection, allowing the gathering of a great variety of types of information (from data on motor behaviours to physiological responses). Basic psychology presents a substantial body of knowledge on which to base self-reports, which permits us to

Table 1. General issues in self-reports

Contents	Operations	Inferences	Questions	Responses	Types
Motor	Accessibility	As data	Verbal tense	Yes/no	Questionnaires
Cognitive	Level of transformation	As sign	Generality vs. specificity	List of responses	Inventories
Physiological	Time: past, present, future, 'usually'			Rating-scales: numbers, adjectives, order	Scales
External events					
Subjective evaluations					

identify the circumstances in which self-reports can be reliable. Finally, we have examined different types of self-reports and their potential weaknesses. Table 1 presents a summary of the most important general issues with regard to self-reports.

It is important to emphasize that biases and sources of error in self-reports and their control, together with the validation of self-reports on non-verifiable events, are areas of research to which serious consideration should be given in the future (Fernández-Ballesteros, 1999, 2002).

SELF-REPORTS IN BEHAVIOURAL CLINICAL SETTINGS

INTRODUCTION

Self-reports have constituted basic procedures of psychological assessment. Self-reports have been used with different goals either in traditional or behavioural assessments. In the first case, the goal pursued is the study of the underlying personality. In the second, the goal to be reached is the measurement of manifested behaviour (verbalized).

Self-reports are widely employed assessment methods, consisting of the collection of verbal information provided by an individual about him or herself. Therefore, it can be considered as a variation of self-observation techniques. Information such as motor responses (avoidance behaviour, tobacco consumption, etc.), psychophysiological responses (tachycardia, sweating, etc.) and cognitive responses (sadness, insecurity, etc.) can be collected through self-reports. It is also the only available method to collect information about cognitive responses (for a review see Fernández-Ballesteros, 2002).

DEFINITION

The term *self-report* includes all structured instruments, generally printed on paper (currently some computerized proofs are available), that will provide information about the subject and his/her behaviour (see Table 1). This study will employ Hersen and Bellack's definition (1988) including questionnaires, inventories and scales, even though their terminology is controversial. Self-reports can be general (referring to the subject's general behaviour) or specific (focused on certain problems or behaviours). A subject's answers constitute a sample of their behaviour and never a sign of any internal element to be known through such answers. Self-reports, as an assessment tool

Table 1. Self-reports in clinical settings

General	Self-Reports	
25T-	General	• Biographical Questionnaire for Behavioural Analysis (Cautela & Upper, 1976) • Fear Survey Schedule I, FSS I (Lang & Lazovik, 1963) • Fear Survey Schedule II, FSS II (Geer, 1965) • Fear Survey Schedule III, FSS III (Wolpe & Lang, 1964) • S-R Inventory of Anxiousness (Endler, Hunt & Rosenstein, 1962) • Body Sensations Questionnaire/Agoraphobic Cognitions Questionnaire, (Chambless, Caputo, Bright & Gallagher, 1984)
Anxiety	Specific	• Questionnaire for Tension and Anxiety Schedule (Cautela & Upper, 1976) • Hamilton Anxiety Rating Scale (Hamilton, 1959) • State–Trait Anxiety Inventory, STAI (Spielberger, Gorsuch & Lushene, 1988) • Maudsley Obsessional-Compulsive Inventory (Hodson & Rachman, 1977) • Beck Depression Inventory, BDI (Beck, Rush, Shaw & Emery, 1979) • Hamilton Rating Scale for Depression, HRSD (Hamilton, 1960) • Modified Hamilton Rating Scale for Depression, MHRSD (Miller, Bishop, Norman & Maddever, 1985)
Depression		• Self-rating Depression Scale, SDS (Zung, 1965) • Attributional Style Questionnaire (Peterson, Semmel, Von Baeyer, Abramson, Metalsky & Seligman, 1979) • Automatic Thoughts Questionnaire, ATQ (Hollon & Kendall, 1981) • Automatic Thoughts Questionnaire-P (Ingram & Wisnicki, 1988) • Gambrill–Richey Assertion Inventory, GRAI (Gambrill & Richie, 1975)
Social skills		• Rathus Assertiveness Schedule, RAS (Rathus, 1973) • Problem Solving Inventory (McFall & Lillesand, 1971)

within clinical contexts, present several advantages that explain its popularity: facility of application, economy, systematizing, allowing results comparison both during the treatment procedure and the follow-up phase. On the other hand, self-reports save time, allowing the psychologist to detect with certain rapidity the areas where the subject may have problems. Consequently, psychologists can evaluate, with more detail, specific behaviours in such areas. In this sense, it allows obtainment of both quantitative and qualitative information that make it possible to design and perform the intervention or treatment. Above all, as it was previously said, self-reports constitute the only direct form of evaluation for subjective cognitive responses.

The studies on the reliability and validity of self-reports have been more frequent in the traditional assessment perspective than in the behavioural assessment field. Its measure presents some problems that may alter the reliability of the obtained data: the subject might distort voluntarily or involuntarily the information. In clinical contexts, the client wants to solve a problem and therefore a voluntary distortion of the data is more difficult. However, there are some factors that might be activated involuntarily such as reactivity and different expectations (the same factors take place within observation and self-observation techniques).

Self-report questionnaires were built by the following three strategies: rational (items are selected by the professional generally following a theoretical model); empirical (items selected showed their capacity to discriminate between different groups of subjects); and factorial (items selected through factorial analysis). The rational strategy is the most used within behavioural assessments.

Areas such as *anxiety*, in a second place *depression* and, in a third place, *social skills* have been developed in the greater majority of self-reports within clinical contexts. The election of the instrument to be used is based on the specific information previously obtained on the case, generally after the first clinical interview. Some self-reports have been elaborated to identify behaviour problematic areas, establishing only the presence or absence of problematic areas (check-lists). However, other self-reports are focused to obtain more specific information on the nature and intensity of the problem. There is a common agreement about the convenience of contrasting and completing the obtained data in self-reports by also obtaining information through direct methods.

Table 1 shows the most used self-reports in the clinical practice. The summary does not intend to be exhaustive, but to provide a small sample. General tools have the goal to identify possible problematic behaviours as well as to obtain information on various aspects that might help to explain the problem. One of the most used is the Biographical Behavioural Analysis Questionnaire (Cautela & Upper, 1976). This questionnaire can be used either as a guide for the interview or to obtain writing responses by the client. If the client responds to it by writing, his/her answers might serve to clarify information.

During the 1960s, several inventories were developed to assess general fears to attend different anxiety problems. They consisted of extensive lists of items to be answered by the client in accordance to the intensity of the fear experienced. These tools were criticized for being unspecific both in the stimulus and the response. These questionnaires are: the Fear Survey Schedule I, FSS I (Lang & Lazovik, 1963); Fear Survey Schedule II, FSS II (Geer, 1965); and Fear Survey Schedule III, FSS III (Wolpe & Lang, 1964) – this last one being the most used of them all. These general self-reports are quite accurate, with moderate convergent validity. Other specific self-report instruments have been developed in regard to anxiety problems to assess several phobias to animals, social phobia, agoraphobia and panic attacks, generalized anxiety, etc.

Other self-reports were developed for depression assessment, especially directed to assess the cognitive manifestations of this problem. The most employed instrument in this area is the Beck Depression Inventory (BDI) (Beck, Rush, Shaw & Emery, 1979). The BDI has been culturally adapted to several countries. Another popular inventory is the Hamilton Rating Scale for Depression (HRSD) (Hamilton, 1960) and its modified subsequent version (Miller, Bishop, Norman & Maddever, 1985), which mainly focused on the psychosomatic and motor components of depression. In addition, the new version includes some cognitive manifestations.

Finally, some self-reports were developed for the evaluation of social abilities, such as the

Gambrill–Richey Assertion Inventory (GRAI) (1975) and the Rathus Assertiveness Schedule, EVENNESS (1973). Both have demonstrated accuracy and validity in measuring assertive behaviour in clinical fields, especially in establishing pre-treatment and post-treatment measures in order to assess therapeutic progress.

FUTURE PERSPECTIVES

The employment of traditional tools (test) for behavioural assessments was rejected for a long time. However, several authors stress their potential usefulness when using the items as indicators of a deficit Basic Conduct Repertory and outlining, consequently, a behavioural analysis of such items. In this sense, the behavioural and traditional assessments could complement each other.

On the other hand, there is a recent tendency to improve psychometric properties of those self-reports employed in the clinical field. The studies that examine the reliability and validity of the different questionnaires, inventories and scales are growing up quickly. This is improving, undoubtedly, their quality as assessment instruments.

CONCLUSIONS

Self-reports were born to be a characteristic assessment technique within the traditional evaluation and personality study. However, the use of these instruments for behavioural assessment is perfectly legitimized since their construction as well as the employment of the provided information are part of radically different presuppositions.

Self-reports represent a great useful set of instruments in the clinical practice as long as they are selected in accordance to previous obtained data on the subject's problem. In addition, it should be understood that the provided information constitutes a sample and never an indicator of some underlying ailment. It is also essential to contrast the information with data provided through direct methods (especially the observation). Finally, the information obtained through self-reports should focus on the accomplishment of a functional analysis that will explain the occurrence of the problem to the clinician.

SELF-REPORTS IN WORK AND ORGANIZATIONAL SETTINGS

INTRODUCTION

Self-report as a method of psychological assessment had its beginning in 1918, when Robert S. Woodworth published the first personality inventory, the Personal Data Sheet. The items (116) were questions to the respondents. For example: 'Do you feel well and strong?' (1) to 'Do you like outdoor life?' (116). The response format was Yes/No. The inventory was developed during the latter stages of World War I to aid mental health officers in the US Army to identify recruits who might be susceptible to psychometrics (Dubois, 1970). Later on, Robert G. Bernreuter modified the Woodworth inventory and applied it to US business and industry for the purposes of personnel selection, placement, transfer and retention–termination (Berneuter, 1931).

From these early beginnings throughout the 20th century to the present, self-report psychological assessment instruments have flourished; some with varying degrees of successes, and others with controversial criticisms. Among these measurement instruments predominantly have been personality questionnaires and inventories, interest inventories, social attitude inventories, adjustment inventories, character tests, scales to measure the self-concept and inventories of self-description as a report of typical behaviour of individuals (Cronbach, 1960: 442–444). Concurrent with the growth in development of self-report measurement instruments there has been a commensurate development in statistical methodology, psychometric methodology and measurement techniques. To name a few these are, not necessarily in any order of importance, 'response styles and bias', 'lie scales and honesty', 'ipsative scores', 'Q methodology as a method of factor analysis', 'faking and evasion', 'social desirability', 'forced-choice response categories' and 'preferences for behavioural styles'.

SOME SELF-REPORT INVENTORIES AND SCALES OF LONG STANDING

In this entry, self-report instruments are restricted to those assessing personality of normal people and behavioural types primarily, and those which have been in work and organizational settings over a reasonably long period of time within the 20th century. These assessment instruments are classified in normative (free response) versus adjective checklists and measures of behavioural types or styles.

The self-report assessment instruments that follow have been selected to be described and discussed because they are the ones that have a history of having been developed more than 50 years ago and/or are still widely used even if their development does not span the last half century. They are also the most popular non-clinical self-report instruments.

Response formats for these instruments vary among 'yes/no', 'check/no check', 'tetrad/pentad

forced-choice' and 'true/false'. These instruments focus on content, purpose, psychometric properties, dates of utilization, strengths, and weaknesses, measurement problems and special features as appropriate. In alphabetical order, the self-report instruments that are discussed include: Adjective Checklist (ACL), Activity Vector Analysis (AVA), California Psychological Inventory (CPI), Gordon Personal Profile Inventory (GPP-I), Guilford–Zimmerman Temperament Survey (GZTS), Hogan Personality Inventory (HPI), Jackson Personality Inventory (JPI), Jackson Personality Research Form (JPRF), Minnesota Multiphasic Personality Inventory (MMPI), Myers–Briggs Type Indicator (MBTI) and Sixteen Personality Factor Questionnaire (16PF).

Adjective Checklist

ACL (Authors: Harrison G. Gough & Alfred B. Heilbrun Jr.) is published by Consulting Psychologists Press (CPP). It is a self-concept measurement that CPP promotes as a personality tool for assessing a normal person's self-awareness and that person's perception by others. Two concepts of multiple inferential selves are measured by 37 scales, including measures of psychological needs, intellect and creativity and ego functioning (CPP, 2000). ACL is a free-response checklist consisting of 300 behaviourally descriptive adjectives from A to Z. The two self-concepts that are measured are the basic self and the ideal self. The ACL was originally developed as a research instrument for the US Airforce (Gough, McKee & Yandell, 1955). It became operational for civilian use a few years later (Gough, 1960) and yielded 6 scales. In the mid-1960s, the ACL was modified and extended to its present form yielding 37 scales (Gough & Heilbrun, 1965). Over the past nearly half-century, it has enjoyed wide acceptance and application in many fields of endeavour including business and industry in team building, personal and career development.

Activity Vector Analysis

AVA (Author: Walter V. Clarke), another early self-report adjective checklist, is a self-concept measuring instrument whose use and application is restricted to clients of the psychological management consulting firm, Walter V. Clarke Associates, Inc., currently located in Pittsburgh, Pennsylvania. Form A was released for operational use by its author in Providence, RI, in 1948, with accompanying reports of psychometric properties and preliminary manual. It was publicly announced to the psychology community 8 years later (Clarke, 1956). Form F is the current form of the checklist consisting of 106 adjectives in free-response format, yielding six scores and three four-factor profiles. The three integrative profiles that are interpreted are measures of the AVA based on the psychological personality theory of Lecky (1945) and the physiological emotions theory of Marston (1928). Respondents are first asked to check those words that they truly believe are descriptive of themselves. Details of the theoretical foundations and empirical applications of AVA are presented in Merenda (1990). For more than 50 years now the reliability and validity of this self-report system has been found to be useful in the world of work and organizational settings. The principal uses have been in pre-employment screening, job selection, personnel management and placement, and transfer and retention.

California Psychological Inventory

CPI (Author: Harrison G. Gough) is a psychological inventory developed more than 40 years ago to assess personality traits of normal persons and to complement or substitute for the primarily clinical MMPI which was designed to measure pathology in clinical settings (Hathaway & McKinley, 1940). Like the MMPI, the CPI in its current third edition has 434 items which are declarative sentences with true/false responses (in the MMPI, the response format was 'true', 'false' and '(?) cannot say'). The 2000 CPP catalogue states that the CPI instrument 'provides an accurate, complex portrait of a client's professional and personal style ... tool to find and develop successful employees, develop leaders, create efficient and productive organizations, and promote teamwork'. That it has survived having more than four decades of adoption and continued use is testimony to its sound psychometric properties.

Gordon Personal Profile Inventory

GPP-I (Author: Leonard V. Gordon) was developed half a century ago as two separate personality assessment inventories (Gordon, 1953, 1956), and they were combined into a single inventory in 1978. Together they measure the personality traits of Ascendancy, Responsibility, Emotional Stability, Sociability, Self-Esteem, Cautiousness, Original Thinking, Personal Relations and Vigour. The Catalogue for Psychological Assessment and Intervention Products (see Psychological Corporation) states that one of the special features of GPP-I is that the response format is forced-choice. This is debatable, and among many psychometricians it is faulty, as will be discussed and explained later on.

Guilford–Zimmerman Temperament Survey

GZTS (Authors: J.P. Guilford, J.S. Guilford & W.S. Zimmerman) is a non-clinical self-report instrument for measuring personality and temperament. Its early developmental beginnings date as far back as 1934 (Merenda, 1999: 910). The GZTS has been used in work and organizational settings since it first became operational more than 50 years ago (Guilford & Zimmerman, 1949). Developed by factor analysis, it yields ten measures of personality traits and three falsification (lie) scales. Over this long period, it has been used in employee and management development according to its current catalogue (CPP, 2000). A psychometric criticism of the affirmative items that comprise the survey is the response format similar to the inital MMPI of yes/no. A caution in the proper interpretation of the 10-score norms are based mainly on college students and have meaning primarily when interpreted ipsatively in relation to other scores in the profile.

Hogan Personality Inventory

HPI (Authors: Robert Hogan & Joyce Hogan) was designed by the authors as an instrument to measure the personality of normal persons primarily for use in personnel selection (Hogan, R., 1986; Hogan, J. & Hogan, R., 1989). The authors state that the HPI does possess similarities to clinical inventories such as the MMPI and NEO-PI. The HPI is a self-report instrument consisting of 206 true/false items that yield, through factor analysis, seven personality scales related to successful job performance.

Jackson Personality Inventory/Jackson Personality Research Form

JPI/JPR (Author: Douglas N. Jackson) are two separate personality inventories designed to be applied in business and industrial settings. JPI-R became operational in 1976 and comprises 300 true/false items. It yields 15 scales organized in five higher order clusters: Analytical, Extroverted, Emotional, Opportunistic and Dependable. The inventory is used widely in settings such as those of work, organizational behaviour or other interpersonal behaviours. JPI-R was preceded in 1964 by the Personality Research Form (PRF) which was designed primarily for personnel selection in industrial and business settings. The current form of PRF is Form E, comprised of 352 true/false items producing 22 scales measuring normal personality.

Myers–Briggs Type Indicator

MBTI (Authors: Isabel Briggs Myers & Katherine C. Briggs) is currently the most widely used as well as misused self-report personality inventory on a world-wide scale.

The instrument determines preferences for behavioural style on four bi-polar scales: Extraversion–Introversion, Sensing–Intuition, Thinking–Feeling, and Judging–Perceiving. The combinations of these four preference scales yield sixteen measures which are interpreted as personality types. Initial work on the development of the MBTI was begun in 1942, and continued until 1962, by the mother–daughter team of clinical psychologists when the Educational Testing Service published it as research instrument. In 1975, CPP became its publisher. Among its wide range of uses in work and organizational settings is management development. However, many business and industrial firms misuse it today for job selection and job placement (see: Merenda, 1990; McCaulley, 1991; Pittenger, 1993).

Personality Factor

PF (Author: Raymond B. Cattell) has been used operationally as an assessment self-report inventory questionnaire for the normal adult personality since 1949. The 16PF personality assessment instrument measures sixteen primary traits plus five second-order factors. It has been widely used in clinical and counselling settings, but just as frequently has been used in industry and business for selection, placement and promotion of personnel by predicting important job related characteristics.

STRENGTHS, WEAKNESSES AND PROBLEMS OF SELF-REPORT

This entry is focused on objective presentation of self-report measures of long-standing in work and organizational settings without evaluating the merits of each instrument or assessment system. However, the presentation would not be complete if attention of the reader were not called to the strengths, weaknesses and problems of self-report, which have only been alluded to so far. Among the strengths of self-report measures is the development of 'lie' or 'honesty' scales and other procedures to detect faking or evasion. Among their weaknesses, especially in the assessment of self-concepts, is the practical inability to control ambiguity in items and individual response styles and biases, particularly to dichotomies, e.g. yes/no, trichotomies, e.g. yes/no, and more so to forced-choice response options, tetrads or pentads. The latter precludes the legitimacy of employing factor analysis methods in the development of instruments and research with the individual items. (Normative measurements are required and it is wrong to use measures in constructing the matrix to be reduced.) Problems also arise with 2-point scores, e.g. yes/no (see Merenda, 1997). Finally, and briefly, many self-report questionnaires that have been developed for clinical use are still being applied in work and organizational settings without justification, thereby producing erroneous, misleading and dangerous interpretations (see: McCauley, 1990; Merenda, 1990; Merenda, 1997).

FUTURE PERSPECTIVES

Beyond the ninth decade of the 20th century, no instruments comparable to the above-mentioned nine have been developed and utilized (Merenda, 1999). This may have been due to two primary reasons: (1) the continuing success of the nine; and (2) the continuing decline of well-trained psychometricians in the USA. However, during this same period, some of the nine have been translated and renormed for application to other cultures with limited success due to inadequate and faulty adaptation procedures. But as expertise and funding in test adaptation methods increase, as they are bound to do as we progress in the 21st century, the future appears promising. At the same time, while the education and training in psychometrics in the USA is definitely declining, in other parts of the world it is steadily rising. It is predicted that in the foreseeable future, correct and effective test adaptation procedures will become a reality and that the influx of well-trained psychometricians outside the USA will result in individual and related cultures producing their own assessment instruments rather than depending on the cultural adaptation of those developed in the USA.

CONCLUSIONS

During the latter half of the 20th century, a number of useful self-report psychological assessment instruments were developed for application in work and organizational settings. Nine of these have been discussed. All have demonstrated their validities and reliabilities for the purposes for which they are intended, as evidenced by their long-standing applications. All nine have been developed and used primarily in work and organizational settings in the USA.

SENSATION SEEKING

INTRODUCTION

The first sensation seeking scale (SSS) was based on the hypothesis that there were consistent individual differences in optimal levels of stimulation and arousal (Zuckerman et al., 1964). The construct of an optimal level of stimulation was first decribed by Wundt at the end of the 19th century and translated into physiological terms by Hebb in the middle of the 20th century. Hebb (1955) also developed an idea of an optimal level of arousal based on the interaction between sensory stimulation and the reticulocortical activation system, a homeostatic neurological system regulating the arousal level of the cortex needed for effective cue function. The development of the first form (II) of the SSS was based on Hebb's construct trying to translate it into behavioural and preference characteristics of individuals.

The development of further forms of the SSS, changes in the theory of sensation seeking, and the research using the scales or other similar scales has

been described in two major books (Zuckerman, 1979, 1994). The most recent definition of the trait from the 1994 book is: 'Sensation seeking is a trait defined by the seeking of varied, novel, complex, and intense sensations and experiences, and the willingness to take physical, social, legal, and financial risks for the sake of such experience' (Zuckerman, 1994: 27).

The earlier theory was based on the neurophysiology of the 1950s, centred around the discovery of the reticulocortical system. Advances in the neurosciences, particularly in psychopharmacology, and the use of animal models to define the trait has changed our conception of the biological basis of sensation seeking. These new models are described in more recent articles and books (e.g. Zuckerman, 1984, 1994, 1995).

DEVELOPMENT OF SCALES

The first experimental form of the SSS included many items that were rationally derived from the idea of a need for intense and varied stimulation. The items were written in a forced choice form with one option representing what was thought to be the choice of a high sensation seeker and the other the choice of a low sensation seeker. The forced choice form was used in an attempt to control the choices for their social desirability values. The items in form I were given to student subjects and their item responses were intercorrelated and factor analysed with the idea of finding one broad general factor from the unrotated item loadings. Form II was based on the items defining this general factor in both men and women.

Subsequent analyses of rotated factors in form II suggested the existence of narrower factors beyond the broad general factor. New items were added to amplify the suggested factors in the experimental form III. These items were again factor analysed but this time with rotation in order to define significant additional factors. Form IV consisted of the General Scale, confirmed by the unrotated first factor in the new study, and four scales consisting of the items loading most highly on each of the four factors. These factors are as follows.

Thrill and Adventure Seeking (TAS)

These are items expressing a desire to try sports or other physically risky activities providing unusual sensations or speed, such as parachuting or scuba diving. All items are expressed as intentions or desires rather than actual experiences. One attitude item that summarizes the factor is: 'I sometimes like to do things that are a little frightening.'

Experience Seeking (ES)

The items describe the seeking of novel sensations and experiences through the mind and the senses, as in music, art, and travel, and through association with unconventional groups and leading a non-conforming life style. An example is: 'I would like to explore a strange city or section of town by myself even if it means getting lost.'

Disinhibition (Dis)

These items describe the seeking as sensation through social activities, parties, social drinking, and sex. An item best describing the factor is: 'I like to have new and exciting experiences even if they are a little unconventional or illegal.'

Boredom Susceptibility (BS)

The items in this factor represent an intolerance for repetitious experience of any kind, including routine work and boring people. Illustrative items are: 'The worst social sin is to be a bore' versus the forced-choice alternative 'the worst social sin is to be rude'.

Form V was developed from form IV in order to provide a Total Score with an equal number of items from each of the four factors to substitute for the General SS score. A new factor analysis was done and the 10 items loading most highly on each of the four factors and not loading substantially on any other factor were included in the test. This last criterion was intended to lower the high correlations among the subscales. Form V consists of 40 forced choice items, 10 for each of the four factors, and a Total Score based on all 40 items or the sum of all four factor scores.

The most recently developed form of the SSS is called 'Impulsive Sensation Seeking' (ImpSS). It is a true–false test of 19 items, 11 of which are sensation seeking and 9 of which are impulsivity items. ImpSS is one of five scales in the Zuckerman–Kuhlman Personality Questionnaire

(ZKPQ, Zuckerman et al., 1993) based on factor analyses of scales and items believed to measure basic traits of temperament and personality. The association of impulsivity and sensation seeking items is a result of the close relationships of scales of both types in a reliable and replicable factor of personality. The sensation seekng items are from form V and some other versions of this type of scale (i.e. 'I like doing things just for the thrill of it'). Items containing mention of specific activities like drinking or parachuting were not included. The impulsivity items are mostly of the type reflecting impulsivity and lack of planning in new activities (i.e. 'I often get so carried away by new and exciting things and ideas that I never think of possible complications'). The two subscales, impulsivity and sensation seeking, may be scored separately.

The usual forms of the SSS are appropriate for older adolescents and adults but not for children. Russo et al. (1993) developed a children's version of the SSS including scales for: Thrill and Adventure Seeking, Social Disinhibition, and Drug and Alcohol Attitudes. Their scale is appropriate for children from 7 to 14 years of age. Various forms of the SSS have been translated into Arabic, Chinese, Dutch, Finnish, French, German, Hebrew, Italian, Japanese, Norwegian, Oriyan, Polish, Spanish, and Swedish. See Zuckerman (1994) for details and publication references or author sources for these translated tests.

Various scales similar to the SSS have been developed by other investigators. Among those correlating highly with the SSS or one or more of its four subscales are: The Change Seeker Index, Stimulus Variation Seeking, Venturesomeness, Reducing–Augmenting, Arousal Seeking, and Novelty Seeking. The last of these, Novelty Seeking (NS, Cloninger, 1987), deserves special attention since a large body of literature, involving psychobiology and psychopathology, is being developed using this scale. NS correlates about 0.7 with ImpSS.

RELIABILITIES

Factor Reliability

A number of studies have attempted to replicate the four factor results of the SSS. Very similar factor structures among the items have been obtained in studies done in Australia, Canada, Israel, and France. Factor reliability coefficients across samples of British and American men and women showed good correspondence of factors for all but the BS scale. Children's versions come up with somewhat different factors as might be expected from the changed nature of the item content. TAS and something like Dis are usually found in the children's versions as well as the adults.

Internal Reliability

Internal (alpha) reliabilities for the SSS V Total Score based on all 40 items range from 0.83 to 0.86 despite the low correlations between some of the subscales. The ranges of reliabilities of the subscales are: TAS, 0.77–0.82; ES, 0.61–0.67; Dis, 0.74–0.78; and BS, 0.56–0.65. BS is the weakest of the four factors, accounting for less variance among items than the others, and this is reflected in its lower reliability. Alpha reliabilities for the ImpSS range from 0.77 to 0.82.

Retest Reliability

Three-week retest reliabilites for the SSS V are 0.94 for the Total Score and 0.94, 0.89, 0.91, and 0.70 for TAS, ES, Dis, and BS respectively. The four-week retest reliability for the ImpSS is 0.87.

DEMOGRAPHIC DATA

Men score higher than women on the Total Score of form V and all of the subscales except Experience Seeking. Scores rise from 9 to 14 years of age, peak in late adolescence, and decline with age thereafter in both men and women. Gender and age differences on the subscales are most prominent on TAS and Dis.

VALIDITY

Phenomenal Expressions

High sensation seekers take many kinds of risk for the sake of novel or intense experiences. They volunteer for unusual experiments like hypnosis and sensory deprivation, engage in extreme or

risky sports like parachuting, hang-gliding, scuba-diving, mountain climbing, auto-racing, white-water canoeing, and fast down-hill skiing. In the military, they volunteer for risky service and are among those who win decorations for heroism during war. They are attracted to high stress jobs like air-traffic control and emergency room medical care. They tend to drive cars at high speeds, recklessly, and under the influence of alcohol.

They tend to take sexual risks, having sex with many partners with a greater variety of sexual activities. There is a high degree of assortative mating based on this trait and those who are markedly discrepant tend to predominate among those seeking marital therapy. Sensation seekers are more likely to be smokers, heavy drinkers, and users of all kinds of illegal drugs. Sensation seeking among preadolescents predicts later drug use. Among drug users, sensation seeking is related to the variety of drugs used rather than specific drugs used.

Sensation seekers are also characterized by preferences in non-risky activities. They prefer live entertainment rather than vicarious experience, but media preferences include films or videos involving sex and violence. They enjoy sex and nonsense humour. They like rock music and dislike blander types of music. In art, they like expressionist types of paintings whereas low sensation seekers prefer peaceful or realistic nature paintings.

Sensation seeking is a normal trait dimension but certain kinds of psychopathology seem to be characterized by high levels of the trait including: bipolar disorder, antisocial and borderline personality disorders, and alcohol and drug abuse. Unipolar depression and schizophrenia tend to be lower on the trait.

Biological Bases

Sensation seeking is based on a biosocial theory and therefore studies of its biological bases are fundamental for construct validity. The trait has a strong genetic basis (60–70%) as estimated from studies of twins raised together or raised apart. The remaining variance is not due to shared family environment but to specific environmental experiences not shared by members of the same family. Several studies have found a specific dopamine-receptor gene accounting for about 10% of the genetic variance, although replication has been spotty.

Psychophysiological studies (Zuckerman, 1990) have shown that high sensation seekers tend to have stronger heart rate orienting responses to novel stimuli but rapid habituation. Sensation seeking is related to augmenting of the cortical evoked potential in response to high intensities of stimulation whereas low sensation seekers tend to have reduced cortical reactions to intense stimuli, indicating a protective kind of cortical inhibition.

Biochemical studies (Zuckerman, 1995) have shown high testosterone levels in high sensation seeking males. High sensation seekers show low levels of an enzyme, monoamine oxidase (MAO), dedicated to the catabolism of brain monoamines, particularly dopamine. Although experimental studies of humans have yet to link dopamine activity with sensation seeking, animal models do indicate a dopamine reactivity in rats with the same physiological and similar behavioural traits.

FUTURE PERSPECTIVES

Use of the ImpSS scale within the framework of a five factor model puts the sensation seeking trait in a context with other basic personality traits. Interactions between traits are important in studies of the phenomena of personality. Sensation seeking continues to be a source of active interest in many areas. A recent computer search of PsyInfo using the term ‘sensation seeking’ yielded 384 abstracts between the last book (Zuckerman, 1994) and March, 2001. This is about the same number as the count between 1979 and 1990. New molecular genetic and biochemical findings confirm the idea that sensation seeking is an evolved, biologically significant trait.

CONCLUSIONS

The construct of sensation seeking has evolved with the continuing research over the last 40 years. Many types of phenomena involving risk-taking, as well as basic preferences in media, art, and music, have been shown to be related to this trait. The trait has shown a strong genetic basis and some of the biological traits that are

genetically transmitted have been discovered. The SSS has evolved along with the construct. Reliability is good and construct validity is broad and significant.

PERSONALITY ASSESSMENT (GENERAL)

SOCIAL CLIMATE

INTRODUCTION

After introducing the conceptual and historical underpinnings of social climate, we describe three key sets of dimensions that characterize it, set out the development and psychometric procedures involved in constructing scales to assess social climate, and cover such issues as scale construction criteria, participants' and observers' perspectives, and environmental preferences. We then review applications, including comparing and contrasting environments and identifying determinants and assessing the impacts of social climate. Next, we consider broader issues involving cross-cultural generalizability, person–environment matching models, and viewing social environments in an ecological perspective. We close by noting that social climate assessment promotes a transactional perspective on the interplay between person and environment.

The social climate is the 'personality' of a setting or environment, such as a family, a workplace, a classroom, or a residential neighbourhood. Each environment has a unique 'personality' that gives it unity and coherence. Like people, some social environments are friendlier and more supportive than others. Just as some people are self-directed and task oriented, some environments encourage self-direction and task orientation. Like people, environments differ in how restrictive and controlling they are. Social climate measures differentiation among environments as personality inventories differentiate among individuals.

The concept of social climate and environmental demands or expectations has a long history. Henry Murray (1938) noted that individuals have specific

needs; the relative strength of these needs characterized personality. Murray's model focused on how the interplay between an individual's needs and an environment's demands influences the individual's behaviour and well-being. He selected the terms alpha and beta 'press' to describe the objective and perceived forces, respectively, that environments place on individuals. Murray's concept of needs led to the development of new procedures to assess personality; more recently there has been a parallel development of measures to assess social climate.

George Stern (1970) noted that descriptions of environmental demands are based on inferred continuity and consistency in otherwise discrete events. In this vein, people form global ideas about an environment from their perceptions of specific aspects of it. When employees help each other with work, take breaks together, and go out of their way to welcome a new employee, the social climate at work is friendly. When neighbours recognize and greet one another, watch one another's homes when they are away, and cooperate to improve the neighbourhood, the neighbourhood social climate is cohesive. Such everyday, real events contribute to people's judgements and impressions of the social climate.

Fundamental advances have been made in the assessment of social climate in the last 30 years. Integrated assessment procedures are available to identify the most important aspects of family, work, educational, and other social settings. Such methods can be used to describe social climates, examine how social climates influence individuals' well-being and performance, understand why some social settings are more cohesive, task oriented, and structured than others, and enable counsellors to help individuals select and create more satisfying and effective life contexts.

UNDERLYING DIMENSIONS OF SOCIAL CLIMATE

A wide variety of settings can be described in terms of three underlying sets of social climate dimensions: relationship dimensions, personal growth or goal orientation dimensions, and system maintenance and change dimensions (Moos, 1994). Table 1 depicts some of the specific dimensions that have been identified in family, work, educational, residential care and treatment facilities, and neighbourhood environments. Relationship dimensions assess the quality

Table 1. Underlying dimensions of social climate

Type of setting	Relationship dimensions	Personal growth dimensions	System maintenance and change dimensions
Family	Cohesion Expressiveness Conflict	Independence Achievement Intellectual–cultural Recreational Moral–religious	Organization Control
Work	Involvement Coworker cohesion Supervisor support	Autonomy Task orientation Work pressure	Clarity Managerial control Innovation Physical comfort
Educational	Involvement Affiliation Teacher support	Task orientation Competition	Order and organization Rule clarity Teacher control Innovation
Residential care and treatment facilities	Involvement Cohesion Support Spontaneity Conflict	Autonomy Practical orientation Self-disclosure	Order and organization clarity Resident influence Staff control
Neighbourhood	Sense of community Neighbouring	Privacy Organization efficacy Entertainment	Informal social control Disapproval of deviance

of personal relationships in a setting. They tap how involved people are, how socially cohesive they are, and how much they help and support one another.

Personal growth or goal orientation dimensions tap the directions in which an environment encourages personal change and development. Because the purposes and goals differ so much from one setting to another, the nature of these dimensions differs as well. In families, personal growth dimensions assess the emphasis on such areas as independence, achievement, intellectual and cultural interests, participation in social activities, and moral and religious values. In the workplace, these dimensions reflect the relative emphasis in such areas as autonomy, task orientation, and work demands. In classrooms, they focus mainly on task performance and competition. In residential care and treatment facilities, this set of dimensions taps treatment goals such as autonomy, practical orientation, and self-disclosure. In neighbourhood environments, they assess activity level, privacy, and the efficacy of neighbourhood organizations (Krupat & Guild, 1980; Perkins et al., 1990).

System maintenance and change dimensions include organization, clarity, control, and innovation. These dimensions measure how orderly and organized the setting is, how clear it is in its expectations, how much formal or informal control it maintains, and how responsive it is to change.

DEVELOPMENT AND PSYCHOMETRICS

Scale Construction Criteria

Researchers typically have used both conceptual and empirical criteria to select items and dimensions for inclusion in social climate scales. A standard set of scale development procedures encompasses (1) reviewing prior literature and research relevant to the specific type of social setting (the focal setting); (2) observing a representative set of relevant settings (e.g. families, work groups, classrooms, or treatment facilities) and conducting semi-structured interviews with participants in these settings; (3) identifying dimensions on the basis of the data and formulating items as indicators of the dimensions; and (4) using the conceptual framework of three sets of social climate dimensions described earlier.

Empirical scale development criteria generally involve the selection of items and dimensions that (1) have a reasonable response distribution; (2) discriminate significantly among the focal settings; (3) are relatively free of social desirability or acquiescence response set; (4) are positively correlated with other items on their dimension; and (5) correlate more highly with their dimension than with any other dimension. Each item also is conceptually related to its dimension and is included in only one dimension so that the dimensions are distinct.

These criteria help to develop internally consistent and reliable subscales that also have good content and face validity. Social climate scales discriminate significantly within each type of setting. They are related to similar constructs in expected ways and are related to external criteria in both concurrent and predictive studies. Social climate measures can stay very stable over time; however, they are quite sensitive to environmental change when it occurs.

Participants' and Observers' Perspectives

In general, researchers have defined and measured social climate in terms of the shared perceptions of the people in that environment. This has the advantage of characterizing the setting through the eyes of the actual participants and of soliciting information about its long-standing attributes in a manner more parsimonious than observational methods. This approach is in the tradition of phenomenological psychology and Murray's (1938) conceptualization of beta press, which reflects each individual's personal appraisal of an environment. It also makes it possible to compare the views of different groups of people, such as parents and children in a family, students and teacher in a classroom, or patients and staff in a treatment programme.

People who are not participants in a setting can also provide their views of what the setting is like. Thus, social workers who make home visits can record and evaluate their impressions of a client's family. Parents and administrators can observe a class and judge the characteristics of

a learning environment. With their impressions from a visit to a treatment programme, members of a patient's or client's family or community volunteers can provide their perspective of a residential facility.

Environmental Preferences

Scales that assess social climate have been adapted to enable respondents to describe their environmental preferences. A researcher can focus on how much people agree with each other about their preferred environment; for example, the family environment parents and children prefer, the type of workplace employees desire, the learning environment teachers and students want, or the areas in which patients and staff have similar goals. For example, the 'real' form of the social climate scales asks people how they perceive a current environment, such as their family or workplace; the 'ideal' form asks people how they conceive of an ideal setting (Moos, 1994). Comparing the real and ideal forms shows how well the current environment matches individuals' preferences, and highlights specific directions for change.

APPLICATIONS

Compare and Contrast Environments

One main application of social climate scales is to compare settings or groups of settings with each other. Usually, these comparisons are made within one kind of environment, for example, to identify differences between families who do versus those who do not have a child with behavioural or psychiatric problems, to see how learning environments in alternative schools differ from those in more traditional classrooms, to compare the environment of a workplace with fixed versus one with flexible scheduling, or to contrast self-help with psychotherapy groups. It is also possible to monitor the change in a setting over time, such as before and after a shift in the orientation and management of a treatment programme.

Although it is less common, some researchers have examined similarities and differences across different types of settings. For example, researchers have compared common aspects of classroom and family settings, such as their level of support and structure; searched for influences of work settings on the family; contrasted community-based and hospital-based treatment programmes; and focused on the links between treatment programmes and group processes.

Identify Determinants of Variations in Social Climate

Researchers have focused on why there is so much variation among social climates; that is, why settings differ in the quality of relationships, emphasis on specific goals and tasks, and level of organization and clarity. The main sets of determinants of social climate that have been examined are (1) the broader context, such as private versus public ownership; (2) physical features, such as the presence of physical amenities and social-recreational aids; (3) organizational structure and policies, such as clarity of rules and freedom of choice; and (4) suprapersonal factors – that is, the aggregate characteristics of the people in a setting.

Studies of how these determinants influence social climate show that, in general, private ownership is associated with more cohesion and organization than is public ownership, clearer, more flexible policies help to create more goal oriented and structured settings, and the presence of mentally and/or functionally impaired individuals dampens involvement and growth orientation. Better physical features tend to promote more cohesive social climates; for example, low-rise in contrast to high-rise housing is predictive of more community solidarity, identification, and involvement (Weenig, Schmidt & Midden, 1990).

Assess the Impact of Social Climate

The social climate of a setting is related to specific aspects of individuals' well-being, such as morale, self-esteem, physical and mental health, adaptation to transitions and crises, and recovery and relapse after psychiatric or medical treatment. Researchers have identified important consequences of family settings (Coon et al., 1990), work settings (Hopkins, 1990), learning environments (Manor, 1987), treatment programmes (Moos, 1997), and neighbourhood environments (Perkins et al., 1990).

In general, environments promote qualities that fit with their dominant aspects. For example, children in families that value independence, achievement, and intellectual and recreational pursuits are likely to show more personal and social competence. A learning environment that emphasizes task performance and academic pursuits tends to promote student achievement. Patients in treatment programmes that emphasize independence and practical orientation tend to improve in social and vocational functioning. Residents are more likely to participate in the activities and governance of neighbourhoods that are more cohesive and that have more efficacious community organizations.

The way social climate influences people is consistent across settings in that relationship dimensions influence each person's commitment to the setting, personal growth or goal orientation dimensions channel the directions of change, and system maintenance dimensions affect how much change occurs and the personal costs of it. For example, when a setting emphasizes relationship dimensions, people are more satisfied. Positive relationships foster commitment and motivation, reduce absenteeism and dropout rates, and make the setting more stable. Cohesion in particular strengthens the influence of personal growth dimensions.

BROADER ISSUES

Cross-Cultural Generalizability

Almost all of the scales that assess social climate were initially developed either in the United States or in other English-speaking countries. Accordingly, there was some concern that the conceptual and empirical rationale underlying these scales might have limited cross-cultural applicability. However, experience over the last two decades in more than twenty European and Asian countries indicates that, in general, the same underlying patterns of social climate dimensions can be identified in a variety of cultural contexts (for examples, see Asai & Bechtel, 1990; Harty & Hassan, 1983; Manor, 1987; Schneewind, 1987; Weenig et al., 1990). Overall, the concepts and methods involved in the assessment of social climate seem to generalize across diverse cultural contexts, but much more research remains to be done in this area.

Person–Environment Matching Models

As noted earlier, there are some important connections between characteristics of social settings and individuals' well-being, performance, and personal development. However, part of the influence of contextual factors depends on the personal orientation and preferences of the individuals who experience them. Pursuing this idea, some investigators have linked the congruence between individuals' preferences and social climate to individuals' outcomes.

The Conceptual Level (CL) matching model provides a developmental perspective for this area. The model posits that more mature individuals are able to organize their own environment, whereas those who are less mature need the stabilizing influence of a well-structured setting. For example, externally oriented individuals tend to adjust better in well-structured settings, whereas internally oriented individuals do better in more flexible environments. Similarly, people who want to explore and shape their environment and who exhibit a strong need for independence profit more from less structured environments.

These findings point to some potentially robust forms of person–environment congruence. As noted earlier, environmental systems tend to maintain or accentuate personal characteristics congruent with their dominant aspects. But when environmental demands either exceed individuals' preferences or tax their capacity to manage them, some personal dysfunction is likely to occur. Moderate emphasis on system maintenance factors helps to promote ego control among individuals who need or prefer a well-structured setting. But a strong focus on these factors, especially among developmentally mature and internally oriented persons, restricts individual growth and can foster passivity. Expressive relationships typically promote morale, but highly independent or introverted persons who prefer fewer social bonds can feel hemmed in or overstimulated by interaction-oriented settings.

Social Environments in an Ecological Perspective

To understand social settings, it is important to consider how the characteristics and influences of

one type of setting may be altered by other factors in individuals' lives. For example, the influence of the workplace is one important aspect of understanding family functioning in a broader social context (Eckenrode & Gore, 1990). In this respect, three patterns of work–family interface have been identified. One is a pattern of positive carryover, when personal gratification and information from work enrich the family. A more common pattern is one of negative carryover, in which work overload and job role conflict cause stressors that create tension in the family. The third pattern occurs when individuals try to conserve their energy and privacy and become less available to family members.

There are important connections between specific aspects of work, an individual's values and patterns of interaction in family and leisure settings, and his or her children's cognitive development and personal orientation. For example, persons who work in entrepreneurial settings value self-control, risk taking, and independent behaviour and socialize their children accordingly. In contrast, persons who work in bureaucratic settings value security and accommodation and teach their children to be obliging and to seek external direction.

Connections between family and school settings are as important as those between family and work, especially with respect to their influence on students' school-related attitudes and performance (Booth & Dunn, 1996). In this respect, some aspects of family and learning environments can amplify each other. Thus, students who are in family and classroom settings which are both high in support and structure tend to have the highest scholastic self-concepts. Stimulating home and learning environments that are more oriented toward learning each independently help to predict more positive attitudes toward school and better academic achievement.

Joint family and school effects are likely to be most powerful when there is psychological continuity between the home and the school. One line of research has shown that youngsters do better in classrooms with rules guiding interpersonal interaction that are similar to those they experience in their families. In addition, parents who are better educated are more likely to mirror the academic style of learning environments at home by praising and interacting with their child, modelling appropriate behaviour, and promoting initiative and independence.

FUTURE PERSPECTIVES AND CONCLUSIONS

The growth of a systems orientation and a focus on the connections between family, work, educational, and other social contexts is an important trend that complements the more established person-centred focus in psychology and the behavioural sciences. This systems perspective has led to an enhanced focus on the differential strength of contextual factors and how cross-situational influences can modify them. The more intensive, committed, and socially integrated a setting is, the greater is its potential impact, especially on personal factors that are changing developmentally. Cohesive, homogeneous settings tend to influence incongruent individuals to change in the direction of the majority, whereas those in the majority maintain or further accentuate their attitudes and behaviour in the relevant areas.

Another development involves examination of the mutual relationships between individuals and the environments they select and create. People actively avoid certain environments and, on the basis of their needs and dispositions, choose to participate in others; in turn, these chosen environments influence people to change in desired ways. In addition, individuals' mood and behaviour may shape their social context, such as when a depressed person's hopelessness and lack of interest leads to a reduction of family support. People construct characteristic microenvironments that then 'reciprocate' by fostering certain attitudes and behaviours. The processes involved in the choice and construction of social environments are closely interwoven with those involved in environmental impact.

Most broadly, social climate assessment has made important advances in the last three decades. From an idea that flowed from Murray's (1938) original concepts of alpha and beta press and the centrality of the social environment in shaping human behaviour, a number of reliable and valid scales have been developed to facilitate the routine assessment of social climate. These advances eventually may

enable psychologists to develop truly transactional models in which person and environment are on an equal conceptual basis as determinants of individuals' morale and well-being.

SOCIAL COMPETENCE (INCLUDING SOCIAL SKILLS, ASSERTION)

INTRODUCTION

Within the process of synthesis, the forming of new relationships among elements and the construction of more and more complex categories, which characterizes scientific behaviour, the social skills concept has evolved from being a molecular operationalization and has focused on overt behaviour to the molar and integrationist consideration of covert responses such as thoughts and feelings, which are, in turn, included within the macroconstruct 'social competence'. Social competence is conceptualized as the variable dependent on a double process of

individual and social evaluation, on the appropriateness of the subject's behaviour according to the demands of the social environment, cultural context, and developmental period.

SOCIAL COMPETENCE

Social competence refers to the general assessment of a person carrying out specific social tasks, with regard to the quality of his performance. In order for a subject to be assessed and graded as 'socially competent', a certain degree of mastery in the skills required to carry out specific social skills satisfactorily is required, but his performance does not have to be exceptional, just satisfactory.

Social competence is the result of the confluence of three sets of variables (Schneider, 1992): (a) *biological and environmental ones*, which influence individuals of the same group and culture in a similar way, so that the group may be perceived as a whole unit with a certain degree of uniformity; (b) *collective experiences*, which give a culture its values and rules, shaping social behaviour and explaining cultural differences, e.g. the Mediterranean culture's emotional expressiveness differs from that of the Japanese; (c) *individual learning*, which is probably the most important social functioning determinant in adulthood and the condition necessary for the development of social competence in childhood and adolescence.

In order to acquire a repertoire of social skills that make up the 'social competence' construct, a child needs to learn a set of basic responses from an early age. For this learning to be possible, on the one hand, conditions of biological normality that do not impose restrictions have to be present, and on the other, an environment that promotes this learning. Personal capacity and environmental resources make up the necessary conditions or requisites for the development of social competence and can be classified into four categories (Hops, 1993): (a) physical and motor, (b) relating to language, (c) relating to the establishment and maintenance of social contact, and (d) upbringing and educational patterns used by the child's parents or tutors.

Social competence depends on achieving three general aims: (a) reaching the goal set by the subject, (b) promoting positive relationships with other people, and (c) obtaining self-satisfaction from the action itself. However, it is not restricted to achieving relevant aims, i.e. affiliation and social support, but the explicit and/or implicit demands of the situation must also be taken into account for the aims to be achieved using socially permitted or positively valued means. The strategy concept referring to the most appropriate way of using social skills assumes that, on the one hand, strategical behaviour is learnt and, therefore, can be modified (Kazdin, 1985; Spivack & Shure, 1974) and, on the other hand, that subjects who relate to others in a socially competent way have the capacity for self-regulation. Both premises lead to the conceptualization of social strategies as a problem-solving process applied to social relationships.

Therefore, social competence not only implies the acquisition of social skills, but also of cognitive strategies directly related to the specific motivational and affective elements of each subject and culture. In this sense, social competence is defined as the learning that enables a subject to relate different cognitive processes to his social experience, which is responsible for beginning, developing, maintaining or modifying the cognitive processes according to the results generated by the subject and his social environment (Yeates & Selman, 1989). The product of this learning is known as 'sociocognitive skills', which, together with those of emotional self-control, are regarded as mediators of the subject's specific responses, in the social relationships process, and which must be assessed, both by the subject and others, as being appropriate, efficient and relevant, and promoting a healthy social adjustment.

Social competence, together with other types of competence (i.e. professional), is one more component within the general framework of personal competence; that is, it is regarded as being a necessary aspect for the development and maintenance of bio-psycho-social well-being, since it is a protection factor against the harmful impact of negative stress factors.

SOCIAL SKILLS AND ASSERTIVENESS

Whereas the term 'competence' refers to the overall assessment, 'skills' refers to the measurement of specific capacities. Research into social skills is

based on three sources. The first and most important contribution comes from *behaviour therapy*. In his book *Conditioned Reflex Therapy*, Salter (1949) used the expression 'excitatory personality' and proposed six exercises for treating subjects with social inhibition; these were (a) expressing feelings openly and without censorship, (b) expressing different emotions easily, (c) expressing opposing opinions when disagreeing, (d) using the first person pronoun 'I', (e) accepting compliments, and (f) improvising. Wolpe (1958), and his disciple Lazarus, carried on with this line of research, replacing the 'excitatory personality' concept with 'assertive behaviour'. Subsequently, Alberti and Emmons published the first book on assertiveness and social skills. In the 1970s, there was an important development in social skills training programmes. We can highlight authors such as Eisler, Hersen, McFall, Goldstein, Kazdin, to name but a few. The second line of research is based on *psychopathology*, with the pioneering contribution from Zigler and Phillips (1960, 1961). They discovered that a patient's level of social competence prior to hospitalization was the best predictor of this social adjustment after being discharged. An inverse relationship between the length of stay in hospital and the relapse rate was also noted. The last precedent is *social psychology*, in which British studies on man–machine relationships was extended to the analysis of man–man relationships (Argyle, 1967, 1969). The behavioural perspective, which highlighted the motor component, complemented the information processing component (perception, decision-making, etc.) so that the assertiveness concept was added to the social skills and sociocognitive concept, and these terms now coexist in scientific literature.

There are two kinds of social skills definitions. Some focus on the functional analysis of relationships between behaviour and their consequences, with social skills being understood as the complex capacity to emit responses with a high probability of obtaining reinforcement or to not emit responses, with a high probability of obtaining extinction or punishment. An example of this type of definition is to regard social skills as the degree to which a person relates to others so that his rights, needs, tastes, etc. are satisfied. Other definitions give priority to the topographical analysis of social behaviour, with emphasis being placed on the appropriateness of the responses (gestures, tone of voice, message, etc.), according to the evaluation by judges and experts. An example of this definition is the degree to which a person relates directly and honestly to others without showing anxiety and without coercion.

In our opinion, the quality criterion prevails over effectiveness, since the contingencies are administered by other people. Thus, whereas aggressive responses are frequently reinforced, i.e. a victim hands over money to a mugger who threatens him with a weapon, socially skilful responses may not have reinforcement, i.e. the boss who refuses to give an employee a deserved pay rise which he has asked for in the correct way due to the company's financial crisis. In any case, both dimensions are interrelated, i.e. quality responses are most likely to be reinforced. Besides, quality responses imply self-reinforcement, the type of reinforcement that depends on the subject.

Therefore, social skills are defined as the basic repertoire of behaviours emitted by an individual in social situations and consist of expressing and receiving opinions, feelings and desires, starting up, holding and ending conversations, defending and respecting personal rights, all in a socially acceptable way and thus maximizing the likelihood of reinforcement and minimizing the likelihood of problems in interpersonal relationships. The elements that integrate social behaviour are grouped into three categories: expressive, receptive, and interactive (see Table 1).

There is no widely accepted classification of social skills. One of the oldest is the one proposed by Lazarus in the early 1970s, which, based on clinical experience, singled out: (a) saying 'no', (b) asking favours and making requests, (c) expressing positive and negative feelings, (d) starting up, holding, and ending conversations. The most common social skills classifications consist of grouping molar behaviours into categories such as opinions, feelings, requests, conversations, or rights. Thus, declarations of love, showing anger, happiness, etc. are expressions of positive and negative feelings. Other classifications use the relationship's aim and the area of application as a criterion, with specific training programmes being set up for the following skills: dating, making friends, public speaking, communication, negotiation, and conflict-solving, etc.

Table 1. Elements of social conduct and inappropriate responses

	Elements	Inappropriate responses
EXPRESSIVE	Verbal	Vague expressions, one-word answers,
What do you say?	(message, speech content)	speaking too much, pet words, insults
How do you say it?	Paralinguistic	Trembling voice, stuttering, shouting,
	(volume, tone, fluency)	monotonous intonation
	Non-verbal	Not looking at the person you are
	(look, facial expression, gestures, posture, closeness, appearance, etc.)	speaking to, facial inexpressiveness
RECEPTIVE	Attention	Thinking about the response instead of
What did they say?	(paid to speaker)	listening to the person speaking
How did they say it?	Perception	Not perceiving the ironical tone in the
	(of the speaker's expressive elements)	speaker's praise
	Evaluation	Evaluating shouts as aggressive responses
	(of the speaker's social responses)	and not as signs of the speaker's nervousness
INTERACTIVE	Length of response	Monopolizing the conversation
How long do you speak for?	(or proportion of time)	
How do you speak?	Turn-taking	Speaking at the same time, frequently
	(regulated by signals such as eye contact, variations in intonation, etc.)	butting in

The terms 'social skills' and 'assertive behaviour' are often used indistinctly in specialized references. However, there is a slight shade of difference between the two concepts. The first one is a more general expression and refers to socially competent behaviour in any interpersonal situation; on the other hand, the meaning of assertiveness is more restricted and is limited to socially competent behaviour of a negative type (disagreement, displeasure, rejection, etc.), especially if a negative reaction or the speaker's opposition is expected, or of a positive type when there is a high degree of uncertainty as to the speaker's response. Having a good time chatting with friends and refusing to lend money to a mate who's a sponger, or successfully telling an attractive girl you love her in front of friends, are examples of social skills and assertive behaviour respectively. From the clinical point of view, deficits in social skills and assertion are extremely relevant due to their association with several disorders (schizophrenia, mental deficiency, delinquency, marital problems, social phobia, depression, etc.).

GENESIS AND MAINTENANCE OF SOCIAL COMPETENCE PROBLEMS

Méndez, Inglés, and Hidalgo (2001) explain the lack of social competence as the result of the interaction of *personal and situational factors* (see Figure 1). The former comprise biological determinants (i.e. hypoacusis), personality variables (i.e. introversion), and basic repertoires of behaviours deficient (i.e. deficit in social skills). The latter include social situation demands (i.e. unfounded criticism that requires an assertive response), another person's/other people's characteristics (i.e. the opposite sex) and the context of the interpersonal relationship (i.e. office). Thus, social competence problems are usually caused by the combined action of multiple factors that give rise to poor and/or disliked learning experiences.

The existence of a genetical predisposition in terms of an increased vegetative activation and avoidance behaviour to non-familiar stimuli (i.e. strangers) is assumed. This is known as behavioural inhibition and shows up early on as a difficult temperament and is related to personality variables such as introversion and neuroticism. Individual differences in reactivity to social stimulation in babies can be deduced from this hypothesis.

Social competence also depends on the situation. Thus, most adolescents report that they have more difficulty in asking a stranger on the bus to put out his cigarette because it is bothering him, than in thanking a friend for helping him with his homework (Inglés, Méndez & Hidalgo, 2000). It is therefore easier to carry out a task with social competence when the social situation

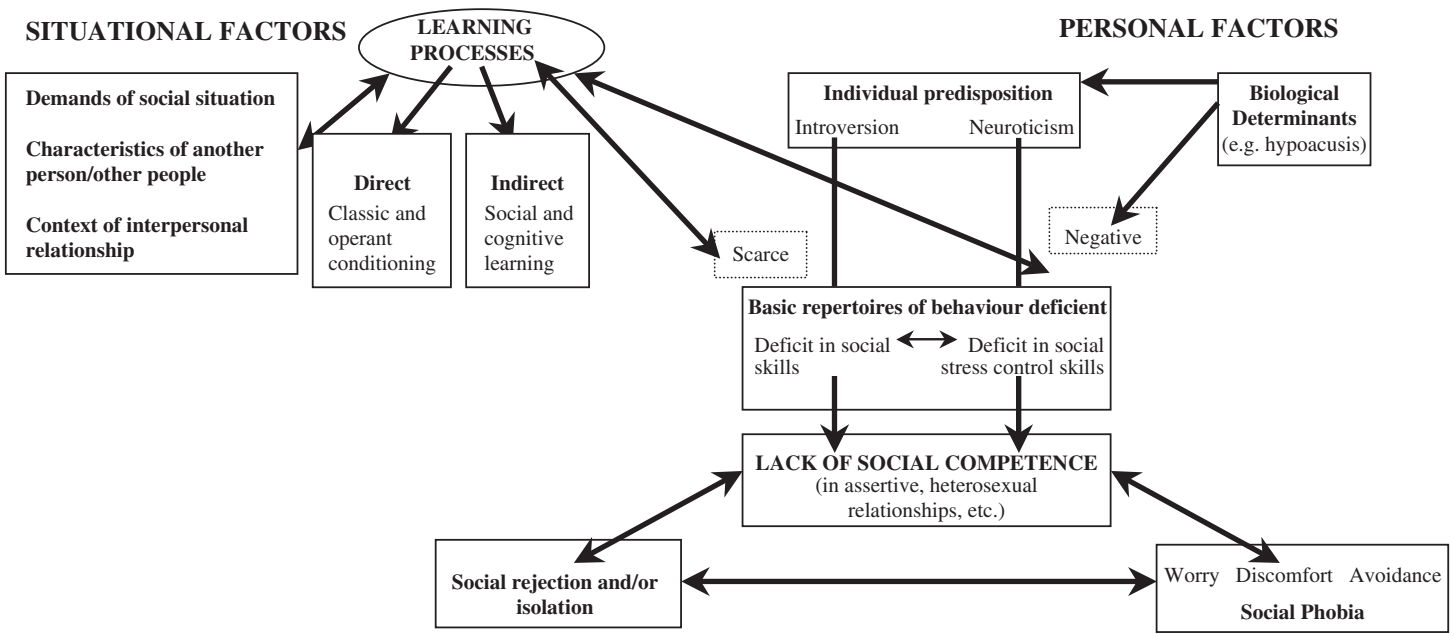

Figure 1. Variables and learning processes responsible for the genesis and maintenance of social competence problems.

demands positive behaviour, the speaker maintains a reinforcing relationship with the subject, and the relationship context is familiar.

The model combines the hypotheses of behaviour consistency and situational specificity, enabling both the specific problems of socially competent subjects, e.g. an adolescent shows anxiety on dates after an extremely negative first experience, and a certain degree of behavioural stability, e.g. a socially reserved adolescent tends to be inhibited in many different social situations, to be explained.

The interaction of personal and situational factors is reflected in the learning history, through direct processes (i.e. 'say please when you ask for something' and a smile after the polite request) and indirect ones (i.e. the model of a socially competent parent). The greater tendency of introverted subjects to avoid social situations results in fewer learning experiences, whereas the greater lability of emotionally unstable subjects increases the likelihood of negative learning experiences. These personal tendencies are greater in situations of isolation and social rejection (i.e. rural areas, ethnic minorities, immigration, etc.) and in environments unfavourable to social development (i.e. authoritarian and punitive educational style, aggressive classmates, etc.). Both poverty and/or aversion to learning experiences make the acquisition of social competence more difficult and lead to the risk of social phobia.

METHODS AND INSTRUMENTS FOR ASSESSING SOCIAL COMPETENCE

In order to assess an individual's social competence satisfactorily, a multimethod–multisource–multicontext assessment must be carried out and should include:

(a) different methods: interviews, questionnaires and scales, sociometric tests, role-play tests, natural observation, self-monitoring, etc.
(b) different sources: subject, partner, friends, parents, teachers, classmates, etc.
(c) different contexts: home, school, work, community, etc.

There are several reasons that justify this proposal. Firstly, the correlation among data obtained using different assessment methods and instruments and for different informants is low. Secondly, the social validity of some of the assessment measures is questionable since there is no agreement on which are the relevant behaviour skills and repertoires that define social competence. This fact makes the preparation of standardized tests for children and adolescents difficult since contrary to what happens with motor development, the development patterns depend on biological maturity to a lesser extent. Thirdly, social behaviour is strongly influenced by the microsocial context (family, friends, etc.) and the macrosocial context (culture, religion, etc.) and presents a high situational specificity.

Questionnaire scales enable relevant information to be collected through the sampling of overt and covert behaviours, in a variety of social situations, from a large number of subjects, in a short time and at a low cost. They are the most frequently used instruments in professional practice due to their efficiency and viability. Table 2 lists some of the most widespread questionnaires and scales in this field. Much information about assessment methods and instruments with children and adolescents can be found in Merrell and Gimpel (1998) and with adults in Caballo (1993).

The aim of social competence assessment is to obtain a subject's health or social adjustment index, i.e. to show to what degree a person can relate in his social context, if he perceives it as comfortable and beneficial, if he positively values it as a factor that promotes personal development and, in short, if he is satisfied with his social environment.

FUTURE PERSPECTIVES AND CONCLUSIONS

There are currently two positions regarding the scope of the 'social competence' construct. From a broad perspective, it has been proposed that the concept covers any activity directed towards survival and the subjects' independent adaptation in the social context, whereas from a stricter point of view, it is thought that it should be specifically limited to the area of the subject's social relationships and friendships. This controversy must be cleared up in the near future.

Table 2. Selected questionnaires for assessing social competence, social skills, and assertiveness

Questionnaire	Author	Age[a]
-Personal Report of Confidence as Speaker	Paul (1966)	1
-Wolpe–Lazarus Assertiveness Scale	Wolpe & Lazarus (1966)	1
-Fear of Negative Evaluation Scale	Watson & Friend (1969)	1, 2
-Social Avoidance and Distress Scale	Watson & Friend (1969)	1, 2
-Rathus Assertiveness Schedule	Rathus (1973)	1, 2
-Assertion Inventory	Gambrill & Richey (1975)	1, 2

-Assessment of Interpersonal Relations	Bracken (1993)	2
-Scales of Social and Personal Competence Skills	Botvin et al. (1997)	2

[a]1 = Adults; 2 = Adolescents; 3 = Children.

Another outstanding question is the lack of consensus on behaviours considered to be socially skilful or competent in any one context. Clinical experience reveals how the same answer given by an adolescent is judged to be assertive by the professional and aggressive by the parent. The social validity problems are shown in the drawing up of standardized tests. How far are the scenes in role-playing tests or the questionnaire items representative of real-life situations of the subjects being assessed? On the other hand, methods such as self-monitoring and non-structured interview, which collect information about the subject's daily life, have the disadvantage of obtaining satisfactory psychometric guarantees.

The level of analysis also poses several questions. Which is the best indicator of social health? Molar assessment of social competence, social skills, or assertiveness? Molecular assessment of the responses, i.e. duration of eye contact? A combination of overall assessments and specific measures or an intermediate level of analysis somewhere between the two extremes is currently being proposed.

Finally, the assessment of motor responses has been developed much more than the assessment of the cognitive and psychophysiological ones. Most instruments assess the subject's verbal and motor behaviour. Less attention has been paid to worries, emotions, and sensations in social situations. Further research should be done into the use of assessing responses such as facial blushing, a characteristic of subjects with problems in this area (social reserve, social phobia, etc.).

SOCIAL NETWORKS

INTRODUCTION

For most of Western psychology, the assumption is made that the person is a distinct and separable object of study. Our efforts to understand the human being and to predict human behaviour have focused largely upon attributes considered to be parts of the individual psyche. This has been true despite theory and confirming evidence to show how interdependent we are with our ecology, our attachments, and our relationships. The dominant approach fails to take cognizance of the degree to which people are in fact interdependent and that the boundaries of the person are actually quite fluid. A full understanding of the individual depends upon an appreciation of the nature, and of the degree, of a person's interdependence with a broader sustaining ecology and, particularly, with contacts with other people.

CONCEPT OF SOCIAL NETWORKS

Network analysis brings the connections among people to the fore. Its early use was in the study

of non-Western cultures. Some anthropologists recognized that their own assumptions about the nature of families, clans, or tribes created a bias in their observations. Rather than assume the nature of the social entity, they instead created a plot describing the actual transactions that occurred among people. Barnes (1972) studied a Norwegian fishing village examining actual interactions and found that they reflected kinship, social class, and work groups. He plotted circumstances in which one person communicated with another only through a third party. He documented occasions in which person A might have separate links with person B and person C, but the relationship between B and C could affect the A–B connection. Bott (1957) studied the marital and family relationships of people in a low socio-economic class. Her use of network analysis permitted her to show how the communication between wife and husband was directly related to the intensity of their separate involvement with their own families and friends. Network assessment has also been used for more general studies of communication and social class (Campbell et al., 1986).

The network is essentially a set of dots (or nodes) and connecting lines (or links). It borrows from an application of graph theory to the visual representation of sociograms or social network maps (Harary, Norman & Cartwright, 1965). The direction of the transactions across the line may be specified and the graph may cover every transaction that occurs, only those that affect a particular individual, or only those that involve a specific commodity such as money or affection. It might also be restricted to in-person exchanges or it may include those by telephone, mail or email. There are many ways to describe a network and many ways to tabulate what occurs within it. To gain a handle on how best to describe an actual network and to see what is revealed by its depiction it is useful to examine the field of network analysis. The theory is largely descriptive and can be useful in the design of surveys (Brugha et al., 1987). One major survey examined who among Canadian seniors provides what kind of help to friends and family members (Stone et al., 1988).

Network analysis can also be applied in the assessment of small group interaction, of organizational communication, and in the analysis of latent patterns or structures that might not appear obvious (Wasserman & Faust, 1994). Network analysis is particularly useful as a means to study the social integration of an individual or of a community (Brissette, Cohen & Seeman, 2000). Wellman (1988), for example, studied the pattern of transactions in an urban community in order to answer the question of just what degree of community existed, i.e. whether people were closely knit into an enduring network of family and friends, active in networks but with frequent changes depending upon circumstances that presented themselves, or relatively isolated from meaningful contacts with others.

Wherever social transactions occur the network can be plotted. This is of great value in social exchange theory where the balance between what is given and what is received is of primary significance (Thibaut & Kelley, 1959). The particular exchange may be considerate caring, the spread of a rumour, or the exercise of power. One study analysed all of the ties (represented by membership in the decision making body of every business, political, fraternal, and human service group) in a town of less than 50,000 people. The authors found a latent, interconnected structure including all the individuals of greatest influence. By examining the overlapping linkages, the authors were able to test the hypothesis that the town's decisions derived from an elite power structure rather than from a pluralistic one (Perrucci and Pilisuk, 1970). Political participation itself has been found to reflect the nature of network ties (Guest & Oropesa, 1986).

SOCIAL NETWORKS AND SOCIAL SUPPORT

The importance of integration into a social network was noted in Durkheim's classic study finding that suicide rates were higher among persons who were not married and who were not linked well to a church or community (Durkheim, 1897/1951). The relevance of social ties to mental health was subsequently noted. Tolsdorf (1976) documented the weak and fragmented networks of psychotic patients. Now, many studies confirm that people better integrated into a social network live longer and are less susceptible to infectious diseases. They are more likely to survive a heart attack and to avoid a recurrence of cancer (reviewed in Brissette, Cohen & Seeman, 2000). These effects appear even when controlling for risks associated with smoking,

blood pressure, and obesity (House, Landis & Umberson, 1988) and therefore highlight the importance of understanding and assessing networks.

Important as social support may be, its definition remains illusive. A comprehensive measure would need to include the quantity of social relationships, the formal structure observable in the pattern of relationships, and the content of these relationships; that is, just what is exchanged (House, Landis & Umberson, 1988). The number of assessment tools for studying social support is legion. Moreover, while measures purport to measure different aspects of support, many of them are actually interrelated (Sarason et al., 1987). Some focus upon the support as it is received or perceived (e.g. Seeman & Berkman, 1988) while others focus upon what is delivered or received (e.g. Barrera et al., 1981). This review deals only with efforts to assess networks but those interested in support measures should refer to a highly useful account by Wills and Shinar (2000) entitled, 'Measuring Perceived and Received Social Support'. Another chapter from the same text (Cohen et al., 2000) deals with the varied theoretical frameworks – social construction, social cognition, symbolic interaction, and relationships – which underlie different approaches to measuring support (Lakey & Cohen, 2000). Here the focus is upon measures that are designed to assess the network. In contrast to measures of received or perceived support, the network model is most appropriate to examine a person's integration within a group and the interconnections of those within that group (Sarason, Sarason & Pierce, 1990).

VOCABULARY OF NETWORKS

Pilisuk and Parks (1986) present a set of terms distinguishing structural qualities – that is, characteristics of the network itself – from functional or interactional terms that refer to what transpires across the links. Structural dimensions include size, composition, accessibility, density, and structural stability. *Composition*, or *source*, are categories identifying individuals in the network, e.g. members of family, attendees at a meeting, people appearing at a government office, or living in a defined neighbourhood. The network might be categorized by the degree of *homogeneity* and *dispersion* (the distance covered by the transactions). *Accessibility* measures the ease in reaching a person in the network. *Density* characterizes the degree to which all members of a network are linked directly to each other whereas *clustering* describes the degree in which members form cliques. *Structural stability* depicts the amount of change in a network over time.

The network is a simple and basic construct but one amenable to a great variety of applications. Network measures vary according to how specific a sub-population is targeted. For example, are only adults included? They vary also in how many network members the respondents are asked to identify and in the types of exchanges that are included (O'Reilly, 1988). Hence, the criteria for who is included will vary. Some identify membership by a minimum frequency of contact within a month's time (Hirsch, 1980). Others focus upon subjective criteria such as closeness, intimacy, or persons who mean a lot to you (Tolsdorf, 1976). Still others use the criterion of formally recognized roles; father, sister, daughter, employer, friend, student, church member, or neighbour (Hong & Seltzer, 1995). Even with discrete roles, the criteria for inclusion are likely to differ. Some measures include anyone cited as a friend or a neighbour. Others use a definition that includes a minimum number of contacts within a given time or add consideration of geographic proximity.

Who is to be included in the network reflects the purpose for which it will be used. House and Kahn (1985) suggest that going beyond a network of five to ten really close relationships yields little in predicting heath outcomes. On the other hand, others have indicated that while a small, densely connected network may be useful for emotional support at critical times, the ability to readjust and to make transitions to new circumstances may reflect the strength of weak, distant, and less homogeneous connections (Vaux & Harrison, 1985).

Functional and interactional qualities describe the relationship of pairs of individuals in a network. In this, we are looking not at the form of the web but at the qualities of the links. We examine such qualities as *frequency* and *friendship duration*. In addition, the *mode* of contact describes the way individuals communicate, such as directly face to face or via telephone or email. *Intimacy* refers to how an individual describes the closeness of a relationship. *Multiplexity* refers to

the number of different exchanges (emotional support, physical help, social contact, or money) that can occur between two individuals. *Symmetry* (see Barnes, 1972) refers to the degree of mutuality or reciprocity in any relationship. *Functional stability* describes changes in the way in which the network is used over time. Surely, ties may be strong or weak, intimate or formal, and reciprocal or unilateral. They may reflect single or multiple role relationships and may be hierarchically ordered in accord with power relationships. The links may be a source of companionship, emotional support, or instrumental assistance (Pilisuk & Parks, 1986). Various scales and measures select aspects of the network of greatest interest to particular assessments. In most cases the source of information about the network of an individual comes from that individual which raises the important issue of informant accuracy (Kilworth & Bernard, 1976).

OTHER NETWORK MEASURES

The concepts noted above have been used as scales and surveys to study neighbourhoods (Buckner, 1988) and urban environments (Wellman & Wortley, 1990). They have been adapted to study the caring for elders among informal and formal providers. One major survey of caregivers of elders was done in Canada (Stone et al., 1988). One scale developed by Antonucci and colleagues, *The social networks in adult life questionnaire*, measures the 'convoy' of continuing, emotionally significant contacts an adult has as she ages (Antonucci & Akiyama, 1987). One of the problems common to the assessment of network characteristics, whether they relate to the various types of social support perceptions and interactions or to other properties of relationships, is the matter of how to determine reliability about what has actually transpired. Coriell and Cohen (1995) draw attention to the disparity frequently seen in reports of supportive interactions by the person offering them and the person receiving them. Such differences, along with variations in the satisfaction people experience from their networks, play an important part in determining loneliness and other aspects of social adjustment (Stokes, 1985). Reis and Collins (2000) provide an excellent account of the issues involved in obtaining reliable indicators for a variety of social interactions and for examining differences between the network as depicted and the degree of satisfaction that occurs with it.

ILLUSTRATING A NETWORK MAP

Network assessment can have clinical uses as well. Among family therapists, one major direction of work has been the effort to plot and to rekindle relationships between the individual and the family of origin (Bowen, 1978). Also, family network therapy has aimed at rekindling the broader network as the actual agent for intervention at times of crisis (Speck & Attneave, 1973). A measure that is particularly well designed for use in clinical practice is the Personal Network Map. It was developed by Carolyn Attneave and reflects her work in developing family network therapy. Individuals list their known family and non-family acquaintances and then place their initials in a set of concentric circles according to their closeness. The links between identified persons are then drawn providing individuals with a graphic depiction of their own networks. The emerging web of connections suggests the presence of clicks or clusters as well as disparate transactions that may define different aspects of an individual's life. The exercise includes a piece of the pie reserved for those individuals perceived as a source of primarily negative interactions. Instructions may be modified to permit the entry of pets who often provide critical bonds to people. The entire exercise can be filled out again as an ideal type (or as a future prediction), to display differences between the actual and the ideal. The Personal Network Map is illustrated in Figure 1.

SUMMARY

Social network measurement is a tool for the assessment of connections. Numerous measures have appeared, sometimes assessing the network of a locality, sometimes of the connections of a particular individual. Their most frequent use has been in the assessment of supportive relationships that have been shown to weigh heavily upon an individual's health, well-being

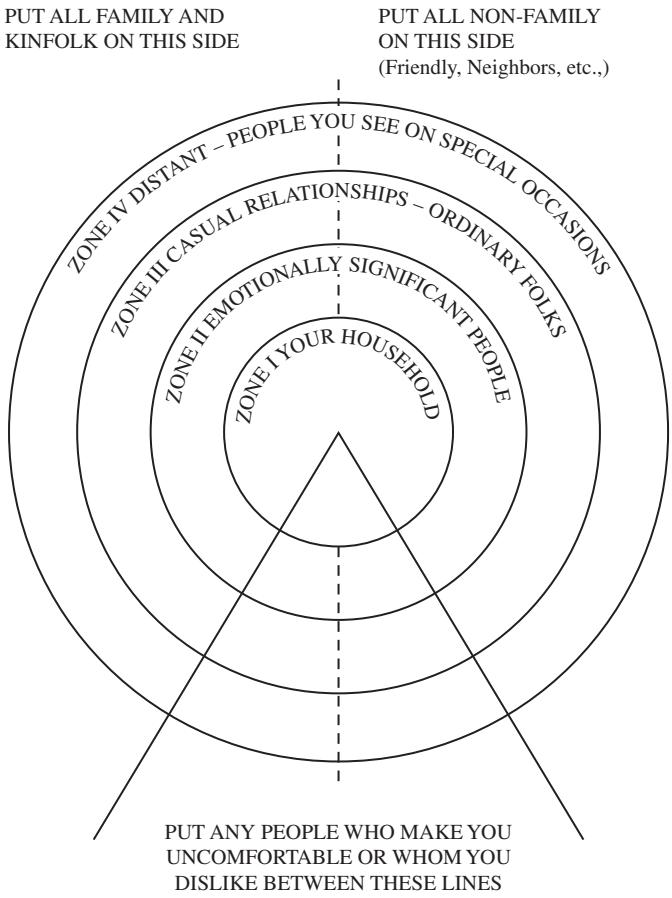

Figure 1. Personal Network Map. (Reprinted with permission from Carolyn Attneave, Department of Psychology, University of Washington, 1978. Distributed by Boston Family Institute, 55 Williston Road, Brookline, Massachusetts 02146.)

and resistance to illness. Other uses include the measurement of a sense of belonging. Community integration, diffusion of information, and political influence have also been studied as reflections of social networks. The major characteristics of social networks that have been studied are summarized in Table 1.

FUTURE PERSPECTIVES AND CONCLUSIONS

Because interdependence is a defining characteristic of the human condition, it is important that social networks be measured. As people become more mobile and distant from their kin, a greater proportion of contacts are transmitted via phone or Internet. The web of communicative contact across the Internet is a phenomenon ripe for network analysis, and studies of Internet support groups have begun. Hopefully, such studies will clarify for us the values unique to sustained face-to-face contacts over enduring periods of time. The plotting of the web of exchange tunes us to look at individuals both as recipients of activities generated by others and as generators of activity as well. It is also consistent with perspectives in feminist psychology and ecological psychology to view human development as a relational activity rather than as an acquisitive one. Concepts of

Table 1. Characteristics of network assessments

Units of study	Group or organization Community or neighbourhood Latent network of transactions Personal networks
Criteria for inclusion	Role relationships (Family member, co-worker, etc.) Formal membership Defined local resident Actual participation Frequent participation Supportive participation
Qualities of the linkage	Uniplex vs. multiplex (Varied transactions) Symmetry Stability Frequency
Functions met by linkages	Information Intimacy Appraisal Social contact Instrumental aid Socio-emotional sharing Negative or hostile contact
Network characteristics	Size Density Clusters Accessibility or Dispersion
Subjective attributes of networks	Embeddedness Satisfaction Sense of belonging Alienation
Mode of communication or contact	Shared membership Phone Mail Email Face-to-face

love, trust, kindness, caring, sharing, giving, receiving, influencing, teaching, belonging, and relating are important parts of the human condition that can only be studied, nurtured, or appreciated by examining an individual's connections to others. Social network analysis is a tool for this task. As network assessment becomes increasingly refined, it will need to sort out the particular network attributes that speak most strongly to richness of the relationships they describe.

SOCIAL RESOURCES

INTRODUCTION

During the past 25 years, a great deal of attention has been paid to the role of the social environment in matters of health, disease, disability, and illness (Cohen, Gottlieb & Underwood, 2000). In particular, many investigators have narrowed their focus to the personal community in which people are enveloped, examining the ways in which family members, friends, neighbours, and co-workers exercise their influence on a multitude of health behaviours, on morbidity, and even on mortality. Persuaded by the evidence documenting the health-protective effects of these personal communities, researchers have designed a variety of social programmes aimed to remedy deficiencies

in certain aspects of the immediate social circle, to enrich its resources, or to compensate for deficiencies by mobilizing support from sources outside the natural network.

Whether conducting basic or intervention research, investigators require measurement tools that are capable of sensitively and reliably gauging relatively objective features of the personal communities that people inhabit, such as their structure and health-related interactions. In addition, there is a need for instruments that assess people's satisfaction with the resources they have received, and measures that tap subjective perceptions of the psychosocial provisions that are available from their social networks. Indeed, the stress-buffering effect of perceived social support has been firmly established in the literature (Cohen & Wills, 1985). In short, depending on the aims of the research, different measurement tools are needed, and each must meet psychometrically acceptable standards of reliability and validity.

Before reviewing specific measures, it is useful to provide an overview of the various dimensions or parameters along which social resources can be measured. Researchers can review these dimensions to identify those that are most relevant to their aims. One comprehensive scheme includes five parameters: (1) the sources of the resources; (2) the types of resources; (3) whether the resources are described or evaluated; (4) whether the resources are received or perceived; and (5) whether the resources flow unidirectionally or bi-directionally (Barrera, 1986).

The first parameter calls attention to the potential value of identifying the particular individuals in the network who actually extend certain resources or from whom the resources are perceived to be available. There is increasing recognition that network members specialize in the kinds of resources they provide, and cannot be substituted for one another in this regard (Cohen, Mermelstein, Kamarck & Hoberman, 1985). Moreover, many support interventions concentrate on improving the quality or augmenting the quantity of the resources provided by particular network members, such as efforts made by home visitors to improve maternal responsiveness to their infants (Olds, Henderson, Chamberlin & Tatelbaum, 1986). The second parameter refers to the varied types of resources and is conventionally designated by the term social support. According to House (1981), social support consists largely of aid, affect, and affirmation, referring to practical help, emotional support, and esteem-raising communications, respectively. In addition to these types of support, socializing and companionship and information and advice are two additional types of social resources that are often represented in measurement tools. Recognizing that different acute stressors or stages of chronic stressors call for different kinds of support, and that the process of stress moderation may differ depending on the kind of support that is measured, it is essential to distinguish among these types of supportive resources.

The third, fourth, and fifth parameters all centre on these types of support, calling for decisions about whether to obtain descriptions of support or to solicit the recipient's evaluations of its sufficiency and quality, whether to gauge the overt expression of support or its perceived availability, and whether to inquire only about the individual's receipt of the resources or about both their receipt and their provision, which reflects a reciprocal exchange of support.

MEASURES OF SOCIAL RESOURCES

The following four questionnaire measures are selected because they are widely used among diverse adult populations, consist of multiple items that demonstrate psychometric strength, and, collectively, cover all the parameters reviewed earlier. Although interview-based measures of social support have been developed, such as the Arizona Social Support Interview Schedule (Barrera, 1981) and the Interview Schedule for Social Interaction (Henderson, Duncan-Jones & Byrne, 1980), only questionnaires are reviewed below. More comprehensive reviews have been conducted by Heitzmann and Kaplan (1988) and Wills and Shinar (2000).

Measures of Perceived Support

Two widely employed measures of perceived support that tap several different types of resources are the *Interpersonal Support Evaluation List* (ISEL; Cohen et al., 1985) and the *Social Provisions Scale* (SPS; Cutrona & Russell, 1987). The former scale has a 40-item version for the general population that taps

esteem, practical/instrumental, informational, and companionship support with 10 items each, and a college student version that includes 48 items tapping the same four resources. Both the internal reliability (alpha) and the test–retest reliability of the general population version are high, in the 0.90 range, with sub-scale reliabilities in the 0.70–0.80 range. In addition to the fact that it does not tap informational support, the ISEL's limitations include the absence of any questions about sources of support and the adoption of a dichotomous (true/false) response format that precludes quantification of the available support and reduces the variance that may be needed to test for stress-buffering effects.

Cutrona and Russell (1987) developed the Social Provisions Scale to assess the six 'provisions of social relationships' proposed by Weiss (1974). It consists of 24 items tapping attachment (emotional support), social integration, reassurance of worth, reliable alliance, guidance, and opportunities for nurturance with four items each. Only practical/instrumental support is missing from this instrument, which also includes an index of reciprocity by inquiring about the respondent's involvement in nurturing others. Cutrona and Russell (1987) report an internal reliability of 0.91 for the entire scale, acceptable sub-scale alphas between 0.65 and 0.76, and a test–retest reliability of 0.75 (over one year). Like the ISEL, this measure does not tie support perceptions to particular network members.

Measures of Received Support

Perhaps, because stress-buffering effects have been largely produced by perceived rather than received support, there is a paucity of measures of the latter construct. Another possible explanation is that any measure of received support should be closely aligned with the demands and needs that arise in the particular stressful context that is being investigated, and such tailoring calls for more laborious instrument development. Whereas the first instrument described below is an example of a generic measure of received support, the second exemplifies a tailored measure.

Drawing on Gottlieb's (1978) classification scheme of informal helping behaviours, the *Inventory of Socially Supportive Behaviours* (ISSB; Barrera, Sandler & Ramsay, 1981) asks respondents about how much or how often they have received 40 kinds of help in the recent past. The 40 items were selected to gauge emotional, practical, and informational support, as well as companionship, but factor analyses suggest that there are five rather than four underlying dimensions, the fifth being support that communicates esteem. Both the internal consistency and the test–retest reliability of the full measure are high, in the 0.90 range. The ISSB does not inquire about the sources of support nor does it solicit the respondent's evaluation of support. Another limitation of the measure is that it does not inquire about whether the respondent needed each type of support before inquiring about its receipt. It is important to ask this question because it allows the investigator to distinguish between people who received low scores because they did not need certain kinds of support from those who failed to receive needed support. Finally, investigators who are considering adoption of this measure should first ensure that all the items are potentially relevant to the supportive needs of the respondents.

A highly tailored measure of support received from a partner or live-in close associate for smoking cessation was developed by Cohen and Lichtenstein (1990). The *Partner Interaction Questionnaire* (PIQ) not only includes 10 items that tap support that aids smoking cessation, but also includes 10 items tapping behaviours that undermine the quitter's efforts (e.g. 'Expressed doubt about your ability to quit'). The latter items spotlight another potential aspect of social resources that can be gauged, namely disagreement, conflict, and other types of unsupportive interactions with close associates. Although the measure mainly taps emotional and practical support and undermining, the two subscale scores that can be derived reflect positive and negative behaviours, yielding alphas of 0.89 and 0.85 respectively (Cohen & Lichtenstein, 1990).

Observational Measures of Supportive Interaction

Out of an interest in understanding how the support process unfolds and sometimes miscarries, and due to evidence that self-reports of perceived and received support are influenced by self-presentational needs (Schwarz, Groves & Schuman, 1998), a handful of investigators have developed tools for observing and recording support-related interactions (Barbee &

Cunningham, 1995; Bradbury & Pasch, 1994). For those planning interventions that mobilize, augment, or specialize the support rendered to others, information about the contextual, relational, and temporal influences on the expression of support is critical.

Based primarily on information obtained from married couples regarding the kinds of support they would appreciate receiving from their spouse when stressful events occur, Cutrona and Suhr (1992) developed the Social Support Behaviour Code (SSBC), comprised of 23 (mainly verbal) behaviours that reflect expressions of emotional, esteem, informational, tangible, and belonging support, along with codes for such negative behaviours as criticism and sarcasm. Application of the coding scheme has mainly occurred in the context of laboratory studies of married couples using a procedure that involves each partner airing a personal problem, which is discussed for 10 minutes, followed by the administration of a questionnaire that is completed by the would-be support recipient who rates the overall supportiveness of the partner's behaviours. The videotape of the support provider's behaviour is then coded by trained observers and yields scores reflecting the frequency of each type of supportive interaction. The mean interrater reliability across the six dimensions is 0.77 (Cutrona & Suhr, 1992), and substantial correlations between the total number of supportive behaviours and both observer and participant ratings of global supportiveness testify to the measure's construct validity (Cutrona, Suhr & McFarlane, 1990).

FUTURE PERSPECTIVES AND CONCLUSIONS

In future research, more attention should be paid to the development of brief screening tools that can be used to determine prospective participants' needs and preferences for extra support. Without such screening tools, intervention candidates may be assigned to a programme that provides types of support that are redundant with the support already extended by the natural network, or assigned to a strategy of delivery that is less acceptable, such as when people are assigned to support groups but prefer to interact with a single source of support (e.g. a home visitor). A second direction for the future is to develop more sensitive measures that are capable of documenting aspects of support that are expressions of the ongoing interdependence between people rather than reflecting the ways people help one another during periods of heightened stress. To date, very little is known about how support becomes part and parcel of everyday routines and interactions, giving rise to the perception of support. Equally important, little is known about how to measure the interpersonal processes that undermine this psychological sense of support. The development of measures capable of addressing both of these topics will enrich our understanding of the ways in which human attachments enhance the health and well-being of people facing a variety of challenging life circumstances.

SOCIO-DEMOGRAPHIC CONDITIONS

INTRODUCTION

The need for socio-demographic assessment derives from the fact that, in analysing the findings of social research, whether attitudes or behaviours, certain socio-demographic and socio-economic variables seem to have some explanatory power. Gender, age, occupation, family and/or household structure, education, income, rural–urban residence, and many other such variables, have shown to have a great importance because attitudes and behaviours generally vary according to the different categories in which groups of individuals tend to fall.

In this respect, it may be pertinent to recall that the concept of social status acquired a very concrete meaning in the social sciences after Ralph Linton defined it (Linton, 1936) as the position of an individual within a social system, to which society assigns certain attitudes and expectations of behaviour that are known and accepted by everyone. Thus, when in a particular culture somebody is assigned as a 'mother', everybody within that culture will immediately attach certain attitudes and expectations of behaviour that define that 'status-role', and that need not be specified because they are of general knowledge. Linton differentiated, besides, between 'ascribed' and 'acquired' status. Ascribed status (as gender or age) is easily recognizable and therefore easily and soon assigned to individuals, so that they can learn quickly the attitudes and behaviours that are expected from a particular status. Acquired status (as occupation) is assigned to individuals only after they have demonstrated certain skills or after they fulfil certain requisites. The conceptual pair 'status-role' has been of great importance in sociological theory in order to refer to the structural or dynamic aspects of any social position within a social system (Bendix & Lipset, 1953; Davis & Moor, 1945;

Homans, 1953; Hughes, 1945; Hyman, 1942; Tumin, 1953).

The concept of socio-economic status developed later, mainly as a response to the Marxist concept of social class, defined in many varied ways by Marx himself in different writings (Marx, 1849, 1852), though Dahrendorf (1959) synthesized them many years later. Marx's concept of social class was not only very ideological, but also a clear oversimplification of social reality, and in addition, not easily 'operationalizable'. Those reasons seem to explain why non-Marxist sociologists, and especially North American sociologists, preferred to use less ideological and easy to operationalize concepts, like 'subjective social class' (social class with which one identifies oneself), or the many variations of 'objective social class', or more specifically, social stratification.

More acceptable to North American sociologists was the concept of social class elaborated by Max Weber (1922), who distinguished between social class based in economic aspects (like Marxism) or social estate (or strata) based on the social prestige of the different status. Similarly, Warner (1941–1959) came to the conclusion, when studying the social stratification systems in American cities based on the social relations of individuals, that there is no single system of stratification that might be universally applicable.

MEASUREMENT

Empirical social research during the past fifty years has demonstrated the great difficulties encountered in the operationalization of the Marxist concept of social class (even in agreeing on the abstract meaning of that concept). But there have been many attempts to operationalize the subjective concept of social class self-identification (based on the assessment made by the individual himself) and the more objective concept of socio-economic status (based on the supposedly more objective assessment made by the researcher).

Subjective Assessment

It has become a common practice in social research to use subjective and objective assessment of the different statuses of an individual. Thus, subjective assessment has become increasingly used to supplement the objective assessment of many social positions (statuses) of individuals. Certainly, gender and age are objectively defined in most researches, but other statuses have been measured not only through objective indicators but also through more subjective indicators.

One example might be social class. Independently of a more objective attempt to define the social class to which an individual apparently belongs, it is increasingly common to recur to a subjective definition, that generally consists on asking the individual to identify him/herself with a particular social class. This is generally called subjective social class, and it may consist of a scale with three to seven or even more categories, depending on the researcher's preferences. Place of residence may also be defined subjectively, when the respondent is asked to answer whether he/she lives in an 'urban, semi-urban, or rural area', though the categories may vary in number and complexity.

Self-anchoring scales of ideology are generally preferred to more objective measurement of an individual's ideological orientation. Seven or 10-point scales, ranging from 'extreme left' to 'extreme right', are usually employed. Religiosity self-assessment scales are increasingly used in addition to more objective indicators of a person's religiosity or degree of religious practice. And a similar practice is also increasingly used for assessing the ethnic or 'national' self-identification of the respondent with a particular social group.

But subjective measurement has also a great significance in some apparently very objective socio-demographic assessment, as the employed–unemployed status. It is true that in most researches the respondent is asked to define him/herself as employed (part or full time) or unemployed according to very specific rules (hours worked per week, per month), but it is not less true that many respondents do not comply to those rules. A similar situation has also been found with respect to marital status, if some social and/or economic benefits depend from being married or unmarried. In all those cases the individual may be tempted to give a not very correct answer if some benefit may be derived from it.

Objective Assessment

In spite of the fact that subjective self-assessment by the respondent him/herself are increasingly

frequent, researchers use more objective indicators to assess most socio-demographic statuses of the respondents. Thus, even though gender is not any more the absolute 'ascribed' status that it was many years ago (individuals may identify themselves with a social gender different from the natural or physical gender, or they may even change their gender physically during their life time), gender is generally an objective status, especially at birth, when roles are assigned for early socialization.

Age continues to be a very objective status, though the concept of cohort or age group, or even generation, may have a more subjective component. Education is usually measured through several indicators, like total number of years of formal education, educational levels or degrees attained, age at which the individual stopped receiving formal education. Income is usually measured also through several indicators, like exact income received (annually, monthly) by the respondent (before or after taxes), family income, income categories, and the like. Place of residence may be objectively assessed on the basis of the number of inhabitants, population categories, social categories (village, town, suburb of big city, slum of big city, central city, and other categories). Occupation is measured, more and more frequently, through the ISCO coding categories, which may use up to four digits (9999 potential different occupations).

Very frequently compound indicators or indexes have been constructed on the basis of several indicators. One of the most common is the Socioeconomic Status index. In most cases this index is built on the basis of educational level, occupational prestige and individual's income, though some researchers also include some assessment of life styles (household appliances, house property, second residences, and the like). Each researcher will combine the categories of each individual indicator in a different manner, generally in accordance with his/her research goals.

Another widely used compound index is the Social Position index, developed by Galtung (1976), which combines eight dichotomized socio-demographic characteristics (gender, age, educational level, income level, occupation, sector of the economy, urban–rural residence, geographical centrality) in order to build a scale with nine categories. The peculiarity of this compound index is that it is very much linked to a theory (centre–periphery theory), though other socio-demographic indicators, simple or compound, are also generally related to some theoretical construct.

FUTURE PERSPECTIVES AND CONCLUSIONS

Socio-demographic and socio-economic variables are important for analysing and interpreting survey findings on attitudes and behaviours. Their assessment, however, may be objective or subjective in most cases, as the examples given below show, and it is up to the researcher to decide which he/she prefers to use in each case. Both types of assessment are usually included in the same research, in many cases to show the correlation that may exist between the objective and the subjective measurements (see Table 1). But many socio-demographic variables are usually defined objectively, as happens with gender and age, among others.

The difficulties in the assessment of socio-demographic characteristics are, however, quite varied. In the first place, there is the difficulty of defining theoretically meaningful categories for each indicator and that of deciding whether to use objective or subjective indicators. Researchers will find a great variety of categories used in the literature for each particular indicator, regardless of it being objective or subjective. Secondly, as international comparative research is increasingly used, researchers find it difficult to agree on variables and categories for each variable that are comparable across countries. This is particularly true with respect to educational level, income level, ethnic or 'national' groupings, religious affiliation and practice, and the like. Third, even within a single country one may find that the operationalization of a particular concept has varied through time (the concept of primary education, for example, may mean a certain number of years of education for individuals pertaining to a particular cohort, but it may mean a different number of years for those belonging to another cohort, simply because the length of primary education may have changed through time) and therefore the meaning may be different for different respondents, without the researcher being aware of that problem. In fact, the main problems that researchers will find in assessing socio-demographic or socio-economic status are the general problems that have always

Table 1. Correlation between objective and subjective measurements

Abstract concept	Subjective assessment	Objective assessment
Social class	Self-identification with a social class, subjective social class	Socio-economic status Social position
Religiosity	Self-evaluation of religiosity	Church attendance, frequency of praying, etc.
Ideology	Self-anchoring scale of ideology	Ideological orientation to specific issues
Place of residence	R's definition	Size of place based on population
Ethnicity, national sentiment	Self-identification	Definition based on objective aspects
Employment status	Self-assessment	Defined on the basis of specific requirements

faced social scientists; that is, going from abstract concepts to concrete indicators, and trying to increase the scope of generalizations both in time and space.

SOCIOMETRIC METHODS

INTRODUCTION

Sociometric methods are concerned with the study of the ways people interact with one another in groups. The way in which people in groups choose one another for different activities gives us relevant information about the social status of individuals and about the structure of the group. This technique goes back to Moreno's (1934) original work. Nowadays, a renewed interest in these

methods has emerged due to its rich potential as a measure of social competence and the predictive value of the knowledge of the individual's position in the group in cases of risk behaviours.

The main construct evaluated by the sociometric test is the *social status* or popularity, and it has been defined as 'a general, group-oriented construct that represents the view of the group towards an individual' (Bukowski & Hoza, 1989: 19). The test also allows for the analysis of some group properties that is facilitated by the *sociogram*.

THE SOCIOMETRIC TEST

Sociometric Questions

In its original form, the sociometric test, or nominations technique, was too simplistic. An individual should nominate a number of partners to carry out some activities such as study, work, etc. Sometimes the social status is defined simply by social acceptance or the number of peer nominations to the question *Who do you like the most to ... (LM)?* and sometimes is combined with a measure of social rejection, defined by the number of nominations to the question *Whom do you like the least to ... (LL)?* Northway (1967) suggests that in any test, three or four criteria should be used as the bases for the choices, limited in number, and the questions should be formulated in the conditional mood. Terry (2000) emphasizes that an unspecified number of choices are necessary to locate the full range of choice patterns.

There have been many variations on the sociometric questions. One of them has been the *self-rating* method whereby the subject predicts who s/he will be chosen by. Another method is the *rating-scale* (Maassen et al., 2000) that consists of a 5-point scale next to the name of each group partner. More complex approaches have combined choices data with behavioural descriptions or psychosocial attributes (Coie et al., 1982). In the latter, the individual should nominate the partners who exhibit the target behaviour or attribute (e.g. Who is the most aggressive one in the group?).

Measures Derived from Sociometric Methods

The earliest approach to the quantification of sociometric data was the socio-matrix whereby all the choices are recorded and then added. The number of choices given to the whole criteria provides an indication of the sociometric status. Other indices frequently used to characterize an individual were: rejection, positive expansion, negative expansion, affective connection, perceptive attention, and perceptive realism. Probabilistic models have been also considered to identify individuals who receive greater or fewer choices than they would receive by chance.

The social status definitions vary depending on whether acceptance or rejection scores are combined or whether acceptance alone is used. Peery (1979) emphasizes that the positive and negative nominations should be combined into two new dimensions of sociometric status: Social Impact (SI) and Social Preference (SP). The SI score, which is a measure of social salience, is obtained by adding up the LM and LL nominations ($SI = LM + LL$). An individual's liking score minus his/her disliking score yields a score called *Social Preference* ($SP = LM - LL$). Coie et al. (1982) and Newcomb and Bukowski (1983) refined Peery's system. Coie et al. proposed the *standardized approach* that consists of standardizing the scores within each group. Newcomb and Bukowski (1983) offered an alternative procedure based on binomial probability.

It is also possible to identify groups of individuals. Previous classification systems were based exclusively on the social preference dimension, and they identified two or three groups (i.e. popular/unpopular; high-status, mild-status, low-status). The missing element in these models is a measure of social salience. Coie et al. (1982) addressed this limitation by using both social impact and social preference measures, and they proposed a classification system in five groups: popular, rejected, controversial, neglected, and average.

There are also some interesting indices that reveal some properties of the group structure: cohesion, conflict, and mutual connection.

Graphic Representation of Sociometric Data

The *sociogram* provides a two-dimensional display of the sociometric data. It is constructed on the basis of the choices between individuals, may

be symmetric, asymmetric, or non-existent. In its original form, group members were designated by symbols with lines and arrows to indicate the direction of the choice. Northway (1967) introduced the notion of target sociogram, which contained four concentric circles, based on the four levels of probability: significantly above chance, above chance, below chance, and significantly below chance, from the inner to the outer circle. The stars are located in the inner circle and the isolates in the outer one.

Recent usage of sociogram has tended to focus on cliques rather than individuals. An early example is found in Coleman's (1961) analysis of adolescent groups. As we move towards the entire set of relations among individuals that define the group, we turn to quantitative methods used by *social networks analysis*. Many of the methods developed within this methodology can be applied to the analysis of the interactions among the people in a group (Frank, 1998; Wasserman & Gulaskiewicz, 1994).

FUTURE PERSPECTIVES

There are some problematic questions related to the sociometric data which require further research: the relative advantages of peer nomination and rating-scale techniques, the use of limited versus unlimited nominations, and the reliability and the stability of peer status. It is also necessary to explore the relations between data derived from measures of positive and negative nominations, which may not be linearly related.

Recent works from Zachriski et al. (1999) have focused on using the sociometric measures with smaller than usual groups and with a child-focused approach. They demonstrated the clinical relevance of these data.

Some authors find the traditional quantitative techniques of sociometric analysis too weak for an adequate analysis of the complexity of group behaviour. They propose the use of more advanced mathematical methods (Markov chains, graph theory, game theory) and statistical methods (multidimensional scaling, cluster analysis, and logit models) for expanding sociometric applications. Besides, the analytical developments in the social network framework will facilitate the analysis of sociometric data.

CONCLUSIONS

The sociometric methods can be applied in any settings: school, army, sports, companies, etc. However, the main applications are in the areas of Developmental Psychology, Clinical Developmental Psychology, and Educational Psychology (Newcomb et al., 1993). The two-dimensional approach to the study of popularity has proved an important point of departure for a rich empirical research. A substantial body of literature has documented a variety of relationships between cognitive, behavioural, and emotional difficulties and the experience of being rejected by one's peers. Numerous studies agree that childhood peer rejection predicts future psychosocial problems such as delinquency, poor academic performance, bullying, dropping out of school, loneliness, substance abuse, and other indices of disorder.

STANDARD FOR EDUCATIONAL AND PSYCHOLOGICAL TESTING

INTRODUCTION

In late 1999, the fourth version of the *Standards for Educational and Psychological Testing* was released by the three organizations responsible for this and previous versions, the American Educational Research Association (AERA), the American Psychological Association (APA), and the National Council on Measurement in Education (NCME).[1] Previous versions had been released in 1966, 1974, and 1985 under the same or a very similar title. The stated purpose of the 1999 *Standards* is as follows:

> The purpose of publishing the *Standards* is to provide criteria for the evaluation of tests, testing practices, and the effects of test use. Although the evaluation of the appropriateness of a test or testing application should depend heavily on professional judgement, the *Standards* provide a frame of reference to assure that relevant issues are addressed. (p. 2)

Work on the fourth version of the *Standards* actually began in late 1993. The three sponsoring organizations assembled a joint committee of sixteen measurement experts in psychology and education and commissioned them with the task of revising and updating the 1985, or third, version of the *Standards*. The focus of this joint committee's task was not on a complete rewriting of the 1985 *Standards*, but rather on the making of changes in order to reflect recent advances in testing and the expanded use of tests into a number of new areas, such as the use of test results for setting public policy. Noteworthy among these advances or developments the joint committee needed to consider were: (1) increased emphases on the role of consequences of test use in the area of validity; (2) an increased degree of emphasis on performance assessment, and, in particular, on portfolio assessment;[2] (3) the current role of generalizability theory when thinking about issues in the area of reliability; (4) the widespread use of item response theory (IRT) in the processing of examinee responses to test items; and (5) the increased use of the computer in the testing process and in the production of diagnostic feedback information for examinees. In addition, one other important development that was to greatly influence the preparation of the 1999 *Standards* had to do with the use of the 1985 *Standards* on a number of occasions in court litigation. The joint

committee saw no reason to believe that this trend would not continue or even escalate in the first decade of the 2000s, and, hence, needed to be extremely careful in drafting the wording of the 1999 document.

CONTENT OF THE *STANDARDS*

The 1999 *Standards* contains fifteen chapters organized into three parts, as follows:

Part I Test Construction, Evaluation, and Documentation

- Chapter 1 Validity
- Chapter 2 Reliability and Errors of Measurement
- Chapter 3 Test Development and Revision
- Chapter 4 Scales, Norms, and Score Comparability
- Chapter 5 Test Administration, Scoring, and Reporting
- Chapter 6 Supporting Documentation for Tests

Part II Fairness in Testing

- Chapter 7 Fairness in Testing and Test Use
- Chapter 8 The Rights and Responsibilities of Test Takers
- Chapter 9 Testing Individuals of Diverse Linguistic Backgrounds
- Chapter 10 Testing Individuals with Disabilities

Part III Testing Applications

- Chapter 11 The Responsibilities of Test Users
- Chapter 12 Psychological Testing and Assessment
- Chapter 13 Educational Testing and Assessment
- Chapter 14 Testing in Employment and Credentialling
- Chapter 15 Testing in Programme Evaluation and Public Policy

Each of the fifteen chapters of the *Standards* begins with a background section, which contains an up-to-date discussion of the issues in testing related to the title of the particular chapter. The background section also provides an overview of the material to be addressed in detail in the individual standards of the chapter. Following the background section in each chapter are the individual standards for that chapter, and they are printed in boldface type. In many cases, a comment follows the standard, which helps by providing further clarification as to the intent of the standard. Following the standard chapters is an up-to-date glossary of terms used in the preceding text and standards. In total, the 1999 *Standards* comprises 194 pages (including preface, introduction, and index) and contains 264 individual test standards organized within the fifteen chapters.

The joint committee made a number of changes to the 1999 *Standards* when compared to the 1985 version. Noteworthy among these changes are: (1) a new chapter on fairness (Chapter 7) was added; (2) the separate chapters on employment testing and on testing for licensure and certification were merged into one chapter (Chapter 14); and (3) the separate chapters on clinical testing and test use in counselling were merged into Chapter 12 on psychological testing, although part of the material on counselling was included in Chapter 13 on educational testing. These changes were made because (1) the joint committee wanted to emphasize the centrality of fairness issues to the 1999 *Standards* by creating a separate chapter; (2) employment testing and testing for licensure and certification share a common bond in that both in general are related to the workplace and hence could be merged; and (3) the joint committee felt it was important to expand on the varieties of psychological tests listed in the 1985 *Standards* and then to treat all such testing in a single coherent chapter.

One other major change in the individual standards in 1999 when compared to 1985 is that the categories associated with the standards in 1985 (primary, secondary, and conditional) were dropped in 1999. This may have been the most controversial change brought about in the 1999 *Standards*, and the 1999 joint committee went to great length in the introduction to the *Standards* to explain why this was done. Basically, the 1999 joint committee felt they had built sufficient qualifying phrases and caveats into the text of each standard so that categories were no longer necessary.

A procedural change brought about by the 1999 joint committee had to do with the increased level

of involvement of outside organizations in the review process for the *Standards*. At each instance when a draft version of some or all of the chapters of the 1999 *Standards* had been prepared, written comments were solicited from outside organizations and individuals with an interest of any sort in the *Standards*. In total, nearly 8000 pages of comments were received and subsequently reviewed. While this process clearly lengthened the amount of time needed to prepare the 1999 *Standards* for publication, the feedback gained from the process proved to be invaluable to the joint committee and users of the *Standards* ended up feeling more involved in the overall process. The preface to the 1999 *Standards* contains a list of organizations, boards, agencies, publishers, and academic institutions that were heavily involved in the review process.

FUTURE PERSPECTIVES

It is the plan of the three sponsoring organizations that the *Standards for Educational and Psychological Testing* continue to be updated and revised on a regular basis. While at this point no specific date has been set for commencement of activities of a new joint committee, it is unlikely that the sponsoring organizations will again allow 14 years to transpire between versions as was the case between the third and fourth versions. This is because advances in testing are occurring at an extremely rapid rate. For instance, as the 1999 *Standards* was being published, a number of individuals were already finding the validity chapter lacking, and were calling for the articulation of procedures or programmes for conducting validation research that will clearly support the transition of the current conception of validity from theory to practice. This is but one of a number of concerns or issues that are bound to arise as the 1999 *Standards* are used in a variety of testing contexts.

CONCLUSIONS

Over the years, the *Standards for Educational and Psychological Testing* has become the critical document for the codification of the critical fundamental elements in need of consideration in the area of psychological and educational testing and assessment. Regardless of the rapidity of changes in testing theory and practice and the need for further versions of the *Standards*, the basic intent of the *Standards* will not change. According to the 1999 joint committee: 'The intent of the *Standards* is to promote the sound and ethical use of tests and to provide a basis for evaluating the quality of testing practices' (p. 1).

Notes

1 During the period from 1993–1999, the author served as NCME liaison to the joint committee charged with revising the 1985 *Standards for Educational and Psychological Testing* and from 1991–1999 as member and then chair of the NCME Standards and Test Use Committee.
2 A portfolio is a systematic collection of educational or work products that has been compiled or accumulated over time, according to a specific set of principles.

STRESS

INTRODUCTION

According to the relational, or transactional, stress concept favoured by most researchers in the field, stress is a process in which external or internal demands are interpreted by persons in relation to their own resources, values, and goals. Stress occurs if demands are appraised as taxing or exceeding the person's abilities or resources to cope with those demands. The most widely examined manifestations of stress are emotional and biological responses, particularly neuroendocrine, cardiovascular, and immune responses. Furthermore, stress is expected to lead to attempts at coping with the situations perceived as stressful (Cohen, Kessler & Underwood Gordon, 1997; Herbert & Cohen, 1996; Lazarus & Folkman, 1984).

Based on the relational stress concept, assessment of stress includes four main components: (1) environmental demands, usually termed stressors; (2) an individual's subjective evaluations of potentially stressful situations, or subjective appraisals; (3) stress-related emotional responses; and (4) biological stress responses. This entry focuses on approaches to measuring the *psychosocial* components of the stress process, including environmental demands, subjective evaluations of stress, and emotional stress responses. Comprehensive reviews of the measurement of biological stress responses are provided by Cohen, Kessler, and Underwood Gordon (1997).

ASSESSMENT OF ENVIRONMENTAL DEMANDS

In measuring environmental demands, three types of stressful events are usually distinguished: major life events, minor life events, or daily hassles, and chronic stressors.

Major Life Events

The most influential approach to measuring life events was developed by Holmes, Rahe, and colleagues (Holmes & Rahe, 1967). In this approach, major life events are defined as events that require increased efforts to readjust to the changes they induce. The stress potential of life events is particularly seen in the cumulative amount of change brought about by successive events occurring within a relatively short period of time. Accordingly, life event measures usually assess the occurrence of life events over a specified time frame, mostly six months or one year, by means of checklists or interviews.

Checklist Measures

The earliest and most widely used checklist measure is the Social Readjustment Rating Scale (SRRS; Holmes & Rahe, 1967) that contains 43 events such as marriage or retirement. Each event is assigned a standardized weight – called 'life change unit' – based on ratings of the degree of readjustment assumed to be required by the event. The sum of 'life change units' over a given period of time is assumed to represent the environmental stress that a person has experienced. Since the publication of the SRRS, a wide array of different life event inventories has been developed for children, adolescents, adults, and aged persons (Turner & Wheaton, 1997).

Though the checklist procedure is the dominant method for assessing life events, it has spawned serious critique (Herbert & Cohen, 1996; Thoits, 1983; Turner & Wheaton, 1997). One objection concerns the event list *comprehensiveness*. Checklists have been criticized for omitting certain types of events, in particular socially sensitive events, 'non-events' such as not having children, and events that are common in certain socioeconomic and ethnic groups. Given that the social construction of what constitutes a life event varies with sociocultural groups, it is recommended that in addition to including universally important events, event lists should be representative for the particular sociocultural setting under scrutiny.

A second critical issue is the use of event-specific *weights* that are assumed to reflect the events' stress

potential in terms of severity or induced change. In the tradition of Holmes and Rahe (1967), event-specific weights are used that are based on groups of raters. An alternative approach to using social judgements is to ask persons to *subjectively* rate the stressfulness of the events they have experienced (e.g. Sarason, Johnson & Siegel, 1978). Subjective ratings are expected to more fully represent the personal impact of the events and their ramifications. However, the personal perception of an event may be confounded with an individual's psychopathology, and his/her assessments of the outcome (Dohrenwend et al., 1993). Furthermore, subjective weights may confuse stress with a person's coping capacity (Turner & Wheaton, 1997). Generally, empirical findings indicate that the use of either socially derived or subjective weights does not increase the predictive power of event lists compared to simply weighting each experienced event by one. With large samples, the use of regression-based weights is an alternative to using social judgements or subjective ratings (Herbert & Cohen, 1996).

A third argument against life event checklists focuses on the problem that event measures may be *confounded* with outcome variables. Events like 'change in sleeping habits' may themselves be symptoms or indicators of the physical or mental disorders they are intended to predict (Thoits, 1983; Dohrenwend et al., 1993). The methodological problem of confounding notwithstanding, empirical findings suggest that deleting confounded items has little influence on the stress–health relationships. Furthermore, deleting potentially confounded events may alter the psychometric properties of the scale and may lead to the exclusion of events that – while indicating a current disorder – also have a causal impact on a later disorder (Herbert & Cohen, 1996; Turner & Wheaton, 1997).

A fourth argument concerns the *psychometric properties* of checklist measures. Reliability, measured either by the 'fall-off' rate (the distribution of recalled events over time) or by test–retest correlations, has been found to be only moderate. Internal consistency has also been estimated, but it is questionable whether internal consistency is an appropriate measure of life event scales' reliability, because life events cannot necessarily be expected to intercorrelate.

Validity of life event measures has usually been assessed by the degree of agreement between respondents and informants. Interrater agreement was mostly obtained from interviews, showing moderate to high agreement (Thoits, 1983). Generally, reports of life events were found to be influenced by current mood and by personality characteristics, particularly neuroticism that is associated with the perception of more events. Another problem with regard to validity is that experiences might be misclassified in order to fit the life event categories (Herbert & Cohen, 1996).

Interview Measures

Given the methodological problems of checklists, interview measures of life events are usually considered to be preferable to checklist measures. Intensive personal interview techniques incorporate qualitative probes that elicit more precise descriptions of events and their contexts. Interview techniques have been found to yield higher retest–reliability and to be more comprehensive with regard to covering the full range of experienced events than are checklist measures (Herbert & Cohen, 1996; Wethington, Brown & Kessler, 1997).

The most widely used interview methods are the *Life Events and Difficulties Schedule* (LEDS; Brown & Harris, 1978), and the *Structured Event Probe and Narrative Rating Method* (SEPRATE, Dohrenwend et al., 1993). The LEDS is a semi-structured interview used to elicit comprehensive descriptions of life events and chronic difficulties and the circumstances surrounding these events. The interview allows for intensive probing. In addition, social and biographical background data are gathered. Independent raters then evaluate the degree of the long-term contextual threat of discrete events and the severity of chronic difficulties given the nature of the events and the individual context. In the SEPRATE interview, structured probes are used to yield comprehensive descriptions of the experienced events. Each event is then abstracted from the interview material and rated by two independent judges on different dimensions such as desirability and severity. While providing a reliable and valid assessment of life events, interview techniques are extremely costly. The amount of time required for conducting the interviews and rating the answers clearly militates against the use of personal interviews, especially in large samples.

Daily Hassles

In the early 1980s, Lazarus and colleagues began to study relatively minor, but more frequently experienced stressors, termed 'daily hassles', and their positive counterparts, called 'daily uplifts' (Kanner et al., 1981). Respondents are instructed to report the hassles they experienced in the previous month and to rate their severity. Since the publication of the Hassles Scale, other daily event checklists have been developed (review Eckenrode & Bolger, 1997).

Daily hassles are expected to have a stronger relationship to health outcomes than do major life events, because daily hassles are regarded as proximal measures of stress, whereas major life events are distal. However, the methodological and psychometric problems discussed in regard to the major life event checklists also apply to the minor event checklists. These problems include lack of representativeness of the sampled events among varying sociodemographic groups, recall biases, and the problem that some hassles are symptoms of physical and mental disorder.

A theoretically and methodologically attractive alternative to minor event checklists that usually cover a longer time period are *diary designs* that require regular, usually daily, reporting (Eckenrode & Bolger, 1997). The methods used include interval-contingent, signal-contingent, and event-contingent recording. A major advantage of daily records is that they can be used in longitudinal designs, thus providing reliable information about a person's exposure to stress, the interrelationships between events, and the temporal relationships between daily events and daily outcomes. Diary designs also minimize the problem of retrospective recall. However, methods based on daily event recording may be reactive, i.e. they might modify the behaviour they should assess.

Chronic Stressors

Chronic stressors are usually defined as stressful events or conditions that persist over time (Lepore, 1997). Distinct from major and minor life events, chronic stressors comprise the more structured and persistent social and economic conditions that may lead to stress (Pearlin, 1983).

Self-report measures of chronic stress focus on family- and work-related conditions (Lepore, 1997; Herbert & Cohen, 1996). Family and work are the major sources of 'role strain', defined as the persistent duties and conflicts people experience in their engagement in normal social roles (Pearlin, 1983). Generally, role stressor questionnaires are valuable for providing information about subjective perceptions of work or marital roles, but they are inappropriate if used as measures of objective role stressors. As is the case with life events and daily hassles, the methodological problems inherent in self-reports include subjective biases, confounding, and measurement errors due to forgetting stressors, particularly if retrospective measures are used. Furthermore, in existing self-report measures of chronic stress, duration, and frequency of exposure to stressful conditions are seldom measured directly.

Some of the enduring or recurring stressful conditions, especially environmental stressors such as crowding, noise, or crime, and economic conditions such as unemployment, can be assessed by *objective measures*, using archival materials or electronic recording devices. Objective estimates of chronic stressors may also be gained by observational techniques, especially in the work setting. However, observational measures are very time consuming and labour-intensive. Moreover, access to participants may be difficult to achieve, particularly in natural settings. Alternatives to naturalistic observation are laboratory-analogue techniques and informant-based techniques (Lepore, 1997).

ASSESSMENT OF SUBJECTIVE EVALUATIONS OF STRESS

Subjective appraisal of potentially stressful situations is the core concept of the relational, or transactional, stress concept (Lazarus & Folkman, 1984). According to this perspective, environmental demands are not stressful per se, but only if they are perceived as stressful by the individual experiencing those demands. Two types of appraisal processes are distinguished: primary appraisal involves the evaluation of situations in regard to the person's well-being, whereas secondary appraisal pertains to the evaluation of coping capabilities.

Although appraisal is the key concept of the relational stress model, very few measures exist to assess stress-related appraisals. Monroe and Kelley (1997) attribute the paucity of measures partly to the ongoing debate over the theoretical

implications of the appraisal concept. Problems for measurement are due in particular to the assumption that appraisal processes are dynamic in nature, involving the initial perceptions of a situation and the permanent reappraisals resulting from efforts to cope with the situation. The most serious problem raised by the transactional stress concept is that appraisal can hardly be differentiated from other constructs, especially coping and distress. For example, appraising a situation as stressful implies the perception of deficient coping abilities and the experience of negative emotions. Furthermore, subjective appraisals may reflect already existing psychopathology rather than independent processes that precede mental health outcomes.

Two types of appraisal measures are currently used (Monroe & Kelley, 1997). The first consists of *single-item* measures that assess an individual's reactions to a specific situation. Such ad hoc, single-item measures possess face validity, and studies have also attested to their predictive validity. They are useful for assessing immediate responses to a potentially stressful situation, especially in laboratory studies or in the context of daily event reporting.

The second type of appraisal measures includes *multiple-item* scales. The *Perceived Stress Scale* (PSS; Cohen, Kamarck & Mermelstein, 1983) is the most widely used *global* measure of perceived stress. The 14-item PSS was developed to measure the degree to which situations in one's life are appraised as stressful. The PSS has adequate reliability, and empirical findings have confirmed its concurrent and predictive validity. Distinct from the PSS, the 37-item Stress Appraisal Measure (Peacock & Wong, 1990) was developed to assess primary and secondary appraisal with regard to a *specific* anticipated stressful event. An alternative way to measuring the subjective evaluation of stressful events is provided by life event measures that incorporate individualized event ratings.

ASSESSMENT OF EMOTIONAL STRESS RESPONSES

According to the relational stress model, stress appraisal results in negative emotional responses, with the possible exception of appraising a situation as challenging (Lazarus & Folkman, 1984). In this theoretical perspective, affective reactions are indicators or manifestations of stress. At the same time, emotional responses are also commonly used as stress outcome variables, indicating subjective well-being (Stone, 1997). The problem of overlapping constructs that is inherent in the relational stress model is perhaps nowhere more obvious than in the double use of emotional responses as indicators of *stress* and as indicators of *stress outcome*.

Stress-related emotional responses are usually assessed by multidimensional mood adjective checklists that include a number of adjectives describing emotional states. In these assessments, respondents are asked to indicate whether the adjectives reflect their feelings experienced in a given period of time. There exists a wide array of different mood adjective scales. Frequently used examples of multi-dimensional mood adjective checklists are the *Profile of Mood States* (POMS), and the *Positive and Negative Affect Schedule* (PANAS; overview Stone, 1997). Besides the multidimensional mood checklists, measures of specific emotional states, particularly anxiety and depression, are also used. In addition, stress-related emotional responses and general psychological distress can be assessed by widely used multidimensional clinical self-report inventories such as the MMPI-2 (Butcher, Dahlstrom, Graham, Tellegen & Kaemmer, 1989) and the SCL-90-R (Derogatis, 1977, 1983).

Strong emotional responses such as anxiety, anger, guilt and grief may be part of the symptoms of the Posttraumatic Stress Disorder (PTSD). DSM-IV criteria for PTSD include physiological reactivity, cognitive intrusions, anxiety, anger, phobic avoidance of trauma cues, and estrangement from others. Diagnoses of PTSD usually are based on clinical interviews, such as the DSM-IV-related Structured Clinical Interview (SCID; First, Gibbon, Spitzer & Williams, 1996). Frequency and severity of posttraumatic stress symptoms can be assessed by self-report measures such as the *Impact of Event Scale* (Horowitz, Wilner & Alvarez, 1979), the *Trauma Symptom Inventory* (Briere, 1995), or the *Posttraumatic Stress Diagnostic Scale* (Foa, Cashman, Jaycox & Perry, 1997).

CONCLUSIONS

The relational, or transactional, stress model provides the theoretical basis for a detailed and

comprehensive assessment of constructs that are conceptualized as the main components of the stress process, including environmental demands, subjective evaluations of stressful situations, and stress-related emotional responses. The major problem inherent in the relational stress model is that concepts overlap, thus resulting in confounded measures. To deal with these problems, it is strongly advisable to precisely define and specify the research question and the assessment goals and to carefully select appropriate measures. Second, given the specific problems inherent in objective and subjective measures of stress, the use of *multiple* measures is recommendable. A third conclusion that can be drawn from the methodological concerns raised by stress-related measures is the need for *longitudinal* designs in order to fully acknowledge that stress is conceptualized as a process.

STRESSORS: PHYSICAL

INTRODUCTION

This entry describes the measurement of physical environmental stressors and design elements that affect human well-being. We discuss stressors encountered in both outdoor and indoor environments, including residential and work settings.

First, we will describe the three most commonly recognized environmental stressors – noise, crowding and air quality (see Table 1) (Evans, 1999). Second, we will discuss measures of overall housing or building quality. Finally, we will describe specific design characteristics that may have an impact on health or well-being. These features include floor height, architectural depth, and characteristics of floor plan (e.g. enclosure and proximity).

NOISE

Exposure to noise has been empirically linked to both auditory and non-auditory effects. *Non-auditory effects* of noise include physiological detriments (increased heart rate or blood pressure), low motivation, and poor cognitive or attentional performance (Evans & Lepore, 1993; Evans, 2001). *Auditory effects* of exposure to loud sound include short term acuity loss ('temporary threshold shift') and, over time, permanent hearing loss ('permanent threshold shift') (Kryter, 1994). Noise is defined as unwanted sound. In other words, while sound is a physical phenomenon, noise is a psychological phenomenon – bothersome or annoying sound. Typically, noise is measured using the logarithmic decibel (dBA) scale. An increase in

Table 1. Noise, crowding and air quality: measurement summary

Physical stressor	Definition	Measures/metrics
Noise	Unwanted sound	dBA, Leq, Ldn
Crowding	Insufficient space	People/room
Air quality		
Volatile organic compounds	Chemical compounds containing carbon, hydrogen and oxygen	TVOC
Radon	Colourless, odourless, radioactive gas. Part of decay chain of uranium.	picocuries/litre Screening Test, Alpha Track Detector, Grab Sampler
Carbon Monoxide	Colourless, odourless, poisonous gas produced when fuel is burned	ppm (parts per million)
Suspended particulate matter	Mix of solid particles & liquid droplets in the air	ppm
Photochemical smog (ozone)	Produced through a reaction between hydrocarbons and sunlight	ppm

10 dBA is perceived as approximately twice as loud. Exposure to noise is measured over a period of time, often 24 hours. Because noise at nighttime is generally more annoying to people, another strategy is to weigh nighttime noise exposure more heavily than daytime noise (Ldn).

CROWDING

The distinction between density and crowding parallels that between sound and noise. Density is a physical index, whereas crowding depends on an individual's cognitive appraisal of need for space (Stokols, 1972). Often, however, density is interpreted as a measure of crowding. There are two types of density – interior density and exterior density. Exterior density refers to the number of people in a geographic area, such as a square mile, an acre or an urban block. Interior density, in contrast, is typically measured by the number of residents per room in a household. There is considerable evidence that interior density is a more meaningful measure with respect to human health than is exterior density (Baum & Paulus, 1987). Customarily, people-to-room ratios exceeding 1.0 are considered 'crowded', but it is also common to question occupants regarding their perceptions of crowding.

AIR QUALITY

Together outdoor air pollution and indoor air quality constitute another type of environmental stressor: air quality. Indoor air quality issues include volatile organic compounds (VOCs), radon, carbon monoxide, and suspended particulates. A source for air quality information is the Environmental Protection Agency's (EPA) website (www.epa.gov/ebtpages/aindoorairpollution.html).

Volatile Organic Compounds

Volatile Organic Compounds, or 'VOCs', are chemicals (any compound containing carbon, hydrogen, and oxygen) released from building materials, cleaning supplies, paints, paint strippers, aerosol sprays, dry-cleaned clothing, and furniture and finishes. Among the most common VOCs is formaldehyde. Health consequences of VOC exposure include eye, nose, and throat irritation; headaches; loss of coordination; nausea; and damage to liver, kidney, and central nervous system. Often, VOC levels are highest just after a building is constructed and furnished, when 'off-gassing' from carpeting, fabrics, caulking, and other materials occurs. Levels also peak in residential environments due to hobbies such as stripping or painting furniture. Measurements of VOC levels can be taken at several locations within a residence or workplace by taking air samples. The samples are later analysed to yield the total VOC level (TVOC). State Cooperative Extension websites and publications are a good source of information regarding volatile organic compounds and other indoor air quality issues (e.g. www.fcs.uga.edu/pubs/current/R059.html).

Radon

Radon is a colourless, odourless, radioactive gas. It is a part of the decay chain of uranium and can enter a building where the foundation is in contact with contaminated soil. Because radon decay products are solids, they can become attached to dust in the air and be inhaled. The health hazard associated with radon exposure is lung cancer. It is estimated that radon results in 20,000 lung cancer deaths per year in the United States (Brookins, 1990). Radon contamination can be measured using a simple 'screening test' available at hardware stores for about $20. The problem with this technique is that radon levels are only measured for a few days and radon levels vary depending upon factors such as wind conditions and whether the ground is frozen. If radon levels are thought to be high, a better instrument is the 'Alpha Track Detector' (about $30). This can be put in place for 3–12 months for more reliable readings. The least reliable measurement instrument is the 'Grab Sampler', which is favoured by real estate professionals due to its speed and ease of use. The average indoor radon level is 1 pCi/L (picocuries per litre). Laquatra (1998) provides further information regarding radon.

Carbon Monoxide

Carbon monoxide is a colourless, odourless, poisonous gas produced by incomplete combustion. Indoor sources of carbon dioxide include

leaking chimneys and furnaces, back-drafting from furnaces, gas water heaters, wood stoves and fireplaces, automobile exhaust from attached garages, and environmental tobacco smoke. Outdoors, highway vehicle exhaust is the primary source of CO emissions. Vehicle exhaust contributes 60% of all CO emissions nationwide, and as much as 95% of CO emissions in urban areas. In the bloodstream, carbon monoxide reduces oxygen delivery to the body's organs and tissues. At low levels, carbon monoxide causes fatigue. At high concentrations, carbon monoxide causes headaches, dizziness, irregular breathing, confusion, impaired vision, loss of coordination, nausea, and flu-like symptoms. At very high concentrations, carbon monoxide is fatal. Carbon monoxide levels are measured using a carbon monoxide monitor. A special issue of *Indoor and Built Environments* is a resource for information regarding carbon monoxide (Descotes, Crépat & Hoskins, 1999).

Suspended Particulates

Particulate matter is a mix of solid particles and liquid droplets found in the air. Outdoors, fine particles (less than 2.5 micrometres) come from the fuel combustion of motor vehicles, power generation and industrial facilities as well as from residential wood stoves and fireplaces. Coarser particles typically originate from crushing and grinding operations or wind-blown dust (www. epa.gov/oar/aqtrnd97/brochure/pm10. html). Indoors, the primary sources of particulate matter is tobacco smoke. Homes with smokers are likely to have particle levels several times higher than outdoor levels. Both fine and coarse particles can accumulate in the respiratory system and lead to an aggravation of respiratory condition; irritation of eyes, nose, and throat; lung cancer; and premature death. Children, the elderly, and those with asthma are particularly vulnerable to the effects of particulate matter. Suspended particulate levels can be measured using an airborne particle counter.

Photochemical Smog

Photochemical oxidants are produced through a reaction of sunlight with hydrocarbons. The most common of these is ozone. Ozone is a gas that forms in the atmosphere when three atoms of oxygen combine (O_3). Ozone is created at ground level by a chemical reaction between oxides of nitrogen (NO_X), and volatile organic compounds (VOC) in sunlight. While ozone in the stratosphere (a layer 10–30 miles from earth) protects life on the planet from the sun's harmful ultraviolet rays, ozone on ground level or in the troposphere (to 10 miles up) can be harmful to human health as well as to vegetation. Ozone is a major contributor to urban smog. The causes of ground level ozone that contribute to smog include motor vehicle exhaust, industrial emissions, gasoline vapours, and chemical solvents. Exposure to ozone may cause chest pain, coughing, nausea, congestion, and throat irritation. Over a long period of time, ozone exposure may cause permanent damage to lungs (EPA, 1997). Data regarding levels of ozone and other air pollutants in regions throughout the United States can be accessed through the EPA's Automated Information Retrieval System ('AIRS') (see www.epa.gov/airsdata).

HOUSING QUALITY

Housing Quality Scales

Housing quality issues have been linked to health and injury as well as psychological well-being outcomes. Several housing quality scales exist (see Table 2). Bradley and Caldwell (1987) developed a set of home inventory scales (HOME) to measure aspects of the residential environment thought to affect the development of infants and children. There are four versions of this scale – appropriate for various age levels (i.e. infant/toddler, early childhood, middle childhood, early adolescence). The versions of the scale include a modest set of items addressing the physical environment (for example: building appears safe, outdoor play environment appears safe, neighbourhood is aesthetically pleasing, house has 100 square feet of living space per person, rooms are not overcrowded with furniture, house is reasonably clean, house is not overly noisy).

The Purdue Home Stimulation Inventory (PHSI) (Wachs, 1986) consists of several subscales coded by a trained observer. One section specifically addresses the physical environment including interior density, sound levels, room

Table 2. Housing quality and environmental design characteristics: measurement scales

Physical stressor	Relevant domains	Scales	Specific population
Housing quality	Privacy/crowding, infrastructure, hazards, indoor climate, etc.	HOME Inventory Scales (Bradley & Caldwell, 1987)	Children
		Purdue Home Stimulation Inventory (Wachs, 1986)	Children
		American Housing Survey (U.S. Census)	–
		Kasl, Will, White & Marcuse (1982)	–
		Evans, Wells, Chan & Saltzman (2000)	–
		Moos & Lemke (1994, 1996)	Elderly
		Norris-Baker, Weisman, Lawton, Sloane & Kaup (1999)	Alzheimers patients
	Home safety	Consumer Product Safety Commission	Elderly
		Wells & Evans (1996b)	Elderly
Design characteristics	Enclosure, visual access, proximity	Early Childhood Physical Environment Scale (Moore, 1994)	Children

decorations, visual access to the outdoors, and the existence of a stimulus shelter where a child can go to be away from noise and activity. Both the PHSI and the HOME scales primarily focus on parenting and on the social environment within the home.

Several other housing scales specifically address the adequacy or inadequacy of housing conditions that might function as physical stressors. Kasl, Will, White, and Marcuse (1982) developed a 29-item housing quality index based on the American Public Health Association's Housing Survey. The scale developed by Kasl and his colleagues involves residents' ratings regarding the adequacy of basic facilities (e.g. heating) as well as items regarding structural deficiencies rated by trained observers.

The American Housing Survey contains dichotomous questions that are used to designate housing as adequate or inadequate. Items address structural adequacy (e.g. plumbing, heating, electricity) and maintenance quality (roof upkeep, wall or floor conditions, plaster and paint condition, presence of rodents). These panel data target specific addresses (rather than occupants) and are collected every other year by the Bureau of the Census for the Department of Housing and Urban Development (see www.census.gov/hhes/www/ahs.html).

A recently developed housing quality scale was developed with mental health outcomes in mind. The scale includes six housing quality subscales: cleanliness and clutter, hazards, structural quality, indoor climate, privacy, and child resources (Evans, Wells, Chan & Saltzman, 2000). Questions regarding housing quality are coded by a trained rater using a three-point rating scale. For example, the structural quality subscale includes: 'Rate the worst ceiling/wall surface in the room, 0 = more than 1 square foot loose or missing, 1 = less than 1 square foot loose or missing, 2 = good.'

Some housing quality or environmental quality scales measure the adequacy of a setting for a specific population. Moos and Lemke (1994, 1996) developed a detailed instrument for the assessment of the designed environment for older adults. Eight subscales, consisting of 153 dichotomous items, evaluate community accessibility, physical conditions, social and recreational facilitation, prosthetic aids, spatial orientation support, safety hazards, staff support facilities and spatial adequacy. A specialized scale exists for the evaluation of facilities for people with Alzheimer's disease (Norris-Baker, Weisman, Lawton, Sloane & Kaup, 1999).

Home Safety

Safety issues can be particularly a concern for parents with young children (Gärling & Gärling, 1991) and for the elderly (Wells & Evans, 1996a) within the home environment. Potential hazards include uneven or broken stairs and steps, faulty

electrical wiring or space heaters, as well as trip and slip hazards such as electrical cords in walkway, loose rugs or carpets, and wet or slippery bathroom, porch, or balcony flooring. Several scales are directed to the homeowner to assist in self-assessment and remediation of home hazards. Home safety checklists are available from the Consumer Product Safety Commission (CPSC) (for example, regarding older adults, www.cpsc.gov/cpscpub/pubs/701.html) and through Cooperative Extension (e.g. Wells & Evans, 1996b). Data from the CPSC's National Electronic Injury Surveillance System (NEISS) indicate the number of annual injuries involving consumer products – from aerosol cans to zippers. The National Safety Council's (1999) annually published *Accident Facts* is also an excellent source for injury statistics.

ENVIRONMENTAL DESIGN CHARACTERISTICS

Floor Level

There are a variety of environmental design characteristics which may act as stressors on the occupants of a space. Among these possible stressors is *floor level* or *floor height*. Research has focused primarily on the effects of living on higher levels of apartment buildings on the psychological and social well-being of women and their children. Studies suggest that living on higher floors is associated with poor social and psychological well-being of mothers, as well as the disruptive behaviour of children (Evans, Wells & Moch, in press).

The measurement of floor height would appear to be straightforward, but has in fact been approached in various, non-equivalent ways. In some cases high-rise buildings are compared to low-rise buildings. Because this research design includes lower floor residents within the high-rise sample, it may not be equated with a comparison of higher floor residents with lower floor residents within the same building. Typically 'lower' floors are defined as floor four or five and below and higher floors have been variably defined as five and above, or 7 to 10, for example.

There are several environmental design characteristics related to the floor plan of a building and the configuration of furniture or partitions. These include architectural depth, enclosure, and proximity.

Architectural Depth

Architectural depth is defined as the number of spaces that a person must pass through to reach a particular room (Hillier & Hanson, 1984). For instance, if reaching a specific room requires passing through four rooms, the architectural depth of that room is five. Research suggests that architectural depth may be related to environmental stressors due to its potential to moderate the negative effects of crowding on social withdrawal (Evans, Lepore & Schroeder, 1996). Spaces with low levels of architectural depth may exacerbate the effects of crowding, while spaces with high levels of architectural depth can help to mitigate the negative effects. Depth can also directly influence social interaction and privacy.

Enclosure

Enclosure refers to the degree to which a space is open or closed. This concept has been particularly relevant in work environments since the 1960s when open-plan offices or 'Burolandschaft' were introduced by the Schnelle brothers from Germany (Sundstrom, 1986). The intention of this design is to reduce physical barriers (i.e. doors and walls) and thereby increase communication, improve the flow of work and enhance teamwork. Such a reduction in enclosure remains controversial, however. Some argue that it contributes to the environmental stress of a setting by increasing the *visual access* (able to see others) and *visual exposure* (able to be seen by others) of the occupant (Archea, 1977). This makes the regulation of social interaction difficult, increases the likelihood of disturbance due to conversation and noise from others, and may lead to territory or boundary regulation disputes. In school environments, open space plans have been found to elevate levels of distraction due to problems with noise and the frequent lack of a stimulus shelter where children can retreat (Moore, 1987).

Proximity

Proximity issues are similar to those associated with enclosure. While being near to those with whom you work or near to traffic flow or a lounge

area may foster some desired communication, it is also likely to contribute to distraction, unwanted social interaction, and ultimately, stress. The notion of *functional inconvenience* (Festinger, Schacter & Back, 1950) suggests that having some distance between work-mates may promote serendipitous contact and contribute to the generation of new ideas.

One scale that measures several environmental design characteristics of a space is a part of the Early Childhood Physical Environment Scales (Moore, 1987, 1994). This scale focuses specifically on the degree of enclosure (closedness or openness) of day-care settings and other educational facility floor plans, but includes the themes of visual access and proximity as well. The 10-item scale includes visual connection between spaces, closure of spaces, spatial separation between spaces, mixture of large open and small, enclosed spaces, separation of staff areas from children's, separation of functional areas from activity areas, separation of different age groups, and separation of circulation from activity spaces.

FUTURE PERSPECTIVES

Future work addressing the measurement of environmental stressors should focus on the further development of holistic scales that address a wider array of potential physical stressors. In addition, attention ought to focus on the continued development of population-specific (children, elderly, disabled) and on setting – or context-specific (e.g. rural/urban, home/workplace) scale instruments. Research on scale development also needs to consider conceptually relevant processes vis-à-vis the outcome of interest – an index for housing quality to predict respiratory health would likely differ from an instrument used to predict mental health. Furthermore, more attention is warranted regarding the interplay between the social and physical environments we inhabit (Evans, Johansson & Carrere, 1994; Moos & Lemke, 1994).

CONCLUSIONS

This entry provides a brief overview of the measurement of a variety of physical environmental stressors. These include noise, crowding, and air quality as well as housing quality and environmental design characteristics. Due to space limitations we have not covered the assessment of several other settings where physical stressors are salient. These include work environments and healthcare facilities. Furthermore, increasing evidence points to the role of natural settings such as parks, gardens, and wilderness settings to curtail cognitive fatigue (Kaplan, Kaplan & Ryan, 1998).

STRESSORS: SOCIAL

INTRODUCTION

Environmental social stressors include both personal and societal factors. To provide a basic grounding in this field, we begin with a brief overview of definitional issues and theoretical perspectives. Specific illustrative examples of environmental stressors are considered next, followed by an overview of several illustrative assessment techniques, including a summary of their strengths and weaknesses. Finally, we conclude with some thoughts about possible directions for future research.

DEFINITIONAL AND THEORETICAL PERSPECTIVES

'Stress' can be described variously but is most often defined as person–environment demands that tax or exceed the individual's ability to adapt. A 'stressor' is an environmental, social, or internal

demand that requires readjustment and becomes a chronic stressor if present for an extended amount of time (Thoits, 1995). 'Distress' refers to a physical or psychological reaction, that may or may not be brought about by stress. Notable in all definitions of stress is that people respond differently to the same objective events. The nature, cause and effects of those differential reactions is the target of most empirical research on this topic. 'Environmental social stressors' include chronic and ongoing stressors (e.g. chronic strained social relations, chronic illness, and caregiving) which influence the health and well-being of the individual's current and evolving life course. Although the bulk of the literature on stress and coping has focused on life events, recent research suggests that chronic stressors may be more critical in terms of well-being. Thus, the focus of this entry is on chronic stressors.

To fully understand how an environmental social stressor can impact the individual, it is critical to place these experiences within a life span context. Individuals grow and develop over time and are influenced both positively and negatively by their experiences. These experiences often, but not always, have cumulative, both additive and multiplicative, effects on their health and well-being. When considering those factors that influence the occurrence and experience of stress it is critical to take into account those antecedent circumstances, history and life span events that have influenced the existing individual. These include gender, age, socio-economic status (SES), culture, race, ethnic, and religious background as well as historical period.

Thus, we know that children of the Great Depression as adults respond quite uniquely and negatively to stressful events such as job loss and job insecurity. Similarly, adults with a history of child or spousal abuse and other negative social relations may, as adults, react to stressful circumstances in a manner most familiar to them, i.e. by abusing others either socially, physically, or psychologically. But on the positive side, it is also the case that those with uniquely positive social interactions over the course of their life are most likely to engage in similarly positive exchanges as well as to expect support from others in times of stress. While recognizing the potential for life span consistency, one should also note that individuals can and do sometimes actively work to avoid consistency and stability in interactions and exchanges especially when past experience has been negative. Thus, the adult who experienced a childhood of poverty or racism might make especially certain that their own children are protected as much as possible from similar experiences.

Several prominent researchers have offered important theoretical perspectives updating traditional theoretical views of stress. Aldwin (1994) notes that stress and coping research most often focuses on psychosocial adaptation. She urges a recognition of the dual importance of both environmental context as well as personal skills and resources. It is this combination which produces maximum and optimal adaptation. Brown has provided clear and compelling evidence of factors which leave certain people most vulnerable to stress. He has noted that those with early childhood experiences of neglect or abuse, combined with a lack of protective factors (e.g. supportive relationships) and the presence of risk factors both personal and environmental (e.g. low self-esteem, poor marriage), resulted in greater vulnerability to stress and consequent depression. Recently, Brown and Moran (1997) have observed that societal events change circumstances. Thus, poverty during the Great Depression is different than poverty during years of affluence; war torn London is different from London today, and New York is forever changed by the recent World Trade Center terrorist attack.

Moos (e.g. Moos & Schaefer, 1993) has made important contributions to our views of stress which also complement the work of Brown. Most recently his work involving longitudinal designs has reiterated earlier findings indicating that life stressors can be offset by personal and social resources, while the use of certain types of coping such as avoidance coping is now known to be much less adaptive than approach or active coping. These findings are evident in cross-sectional studies but have also been found to predict both vulnerability to and remission from depression. Pearlin's (Pearlin, 1989) work has focused on the stress process. He cautions that we must include background factors such as SES, personal and family history, other resources such as coping and social support as mediators to better understand both primary stressors and secondary stressors as well as the individual's reaction to them. His application of this model to the caregiving situation has offered important insights about why some people are able to successfully cope with the burdens of caregiving

while others are not. Indeed, as Pearlin has shown, context is a critical determining element.

CHRONIC SOCIAL STRESSORS

There are several types of chronic environmental social stressors. Chronic stressors may exist in several domains such as work, financial, housing, relationships, health, and social life (Wheaton, 1994). These chronic stressors could be societal, e.g. racism and discrimination, or they could be individual, e.g. negative social interactions. Chronic stressors from different domains often occur simultaneously with a complex intertwining of several stressors.

Chronic illness, such as arthritis, can be considered a stressor in the health domain. Combine this health stressor with strained family relations, and complex relationships can be assumed to result. For example, chronic social stress may occur for a middle-aged woman balancing multiple roles (worker, spouse, mother) along with pain and difficulty performing everyday activities due to arthritis. These stressors can become overwhelming with the addition of excessive absences from work due to illness and the possible loss of income thus resulting in financial strain. Since chronic stress does not occur in a vacuum, the consideration of independent and interactive effects of multiple chronic stressors is important.

Rather than consider the complex web of stressors in several domains, it is sometimes useful to take a comprehensive look at an individual chronic stressor. Several investigators have focused on the negative stressful interactions that may occur in the caregiver relationship (Parris-Stephens, Townsend, Martire & Druley, 2001; Pearlin et al., 1990). Relationships can be strained when family members have a history of discord or when they cannot agree on how to care for a loved one. A child caring for a parent with Alzheimer's disease may have strained relations with siblings who are perceived as not doing their part. Negative social relationships can coexist with caregiver burden, thus becoming a secondary stressor that can be even more detrimental to well-being than the original stressor (Pearlin et al., 1990).

Another way to look at chronic social stress is in terms of ongoing negative social interactions, possibly as a result of a history of strained relationships among family members (Suitor, Pillemer, Keeton & Robinson, 1995). Early patterns of interaction stemming from childhood can influence relationships over the life course (e.g. parental favouritism, disappointment that a child did not fulfil expectations). It is also often the case that parents and adult children have different perceptions about the quality of their past and current relationships. For these reasons, assessing family conflict from the point of view of both the parent and individual adult children can be especially valuable (Suitor & Pillemer, 2000). Examples of negative stressful interactions include interactions which are overly critical, smothering or overwhelming, make too many demands, and interactions which get on your nerves. Network members can be a source of stress when expectations for support are not met and not having a confidant can be particularly stressful especially in the face of adversity such as financial strain or chronic illness.

SPECIFIC INSTRUMENTS FOR MEASURING CHRONIC STRESS

The measurement of chronic social stress is a critical issue. Table 1 summarizes several key measures. A wide variety of approaches are available to assess chronic social stress including use of self-report measures, structured or semi-structured interviews, and the daily diary method. An array of stress measures are available and described in detail in Zalaquett and Wood (1997; see Derogatis & Fleming and Moos & Moos below) which provides psychometric information for chronic stress measures and for other types of stress measures as well (e.g. daily hassles, major life events). Cohen, Kessler, and Underwood Gordon (1995) also provide a useful guide for measuring various types of stress, including chronic stress. Further, the *Encyclopedia of Stress* (Fink, 2000) is a 3-volume series which details stress across a broad variety of topics and issues.

In this entry, we focus on chronic stress measures. Measures in four areas of chronic stress research are reviewed: (1) comprehensive measures of chronic stress in multiple domains, (2) global chronic stress measures, (3) comprehensive measures of particular interpersonal stressors (e.g. caregiver stress), and (4) global

measures of chronic negative social interactions. The measure should be chosen after careful consideration of the purpose of the study, rather than on any specific or absolute criterion. However, the use of comprehensive, multidimensional measures of chronic stress, whether across multiple stressor domains or within one particular stressor, is generally the preferred method of assessment.

Comprehensive Measures of Chronic Stress in Multiple Domains

The investigator wishing to focus on the contribution of various domains of chronic stressors to well-being should use a comprehensive, multidimensional measure. Moos and Moos (1997) describe the 207-item Life Stressors and Social Resources Inventory (LSSRI) which assesses physical health status, housing and neighbourhood, finances, work, relationships with spouse/partner, children, extended family, and friends and social groups. The LSSRI includes measures of both life stressors and social resources. This measure is somewhat time consuming with the self-report format taking about 30 minutes and the structured interview format taking 30 to 60 minutes to administer. This measure is available in adult form and youth form, thus allowing an examination of chronic stress across a broad age range. Further, the multidimensional nature of this measure allows the assessment of chronic stress across a variety of domains. This measure shows good reliability on both the adult and youth form with alphas ranging from 0.79 to 0.84 for life stressors and social resources. Moos and Moos provide extensive reliability and validity information in Zalaquett and Wood (1997).

The Derogatis Stress Profile (DSP; Derogatis & Fleming, 1997) is a 77-item measure including three overall domains each with several subdomains. The domains are environment (domestic, vocational, and health), personality mediators (time pressure, driven behaviour, attitude posture, role definition, and relaxation potential), and emotional response (depression, anxiety, and hostility). This measure is relatively quick and easy to administer, taking approximately 12 to 15 minutes. The DSP shows good reliability with internal consistency measures ranging from 0.79 to 0.93 for the sub-domains and from 0.83 to 0.88 for the three overall domains. Extensive information is provided on reliability and validity in the Zalaquett and Wood (1997) volume.

Brown's Life Event and Difficulties Schedule (LEDS; Brown, 1989) is yet another useful general chronic stress measure that allows for the examination of multiple domains, such as work and family. This semi-structured interview is particularly useful in its use of contextual ratings from the researcher. Wethington, Brown, and Kessler (1995) and Lepore (1995) provide an overall review of this instrument. The LEDS allows for investigation of select stressors (e.g. work stress), but it is time consuming, and is somewhat controversial in the use of contextual ratings (Lepore, 1995).

Wheaton's (1994) chronic stress scale is a 51-item measure that assesses financial, general/ambient problems, work, marriage, and relationships, parental, family, social life, residence, and health. This measure captures chronic stress across multiple domains, yet is relatively short and easy to administer. See Wheaton (1994) for a detailed description of this measure and its validity, and Turner, Wheaton, and Lloyd (1995) for the actual measure.

Global Chronic Stress Measures

If time is an issue, a shorter, global stress measure may be appropriate. Cohen's Perceived Stress Scale (PSS) is a 14-item measure of appraisal of life stress. This global stress measure assesses the perception that life is unpredictable, uncontrollable and overloaded. The PSS is quick and easy to administer. It is most appropriate for studies on chronic stress in general and less useful in terms of capturing chronic stress in a specific domain. The PSS showed good reliability in 2 college samples and a smoking cessation study sample with alphas equalling 0.84, 0.85, and 0.86, respectively. Further psychometric information is available from Cohen, Kamarck, and Mermelstein (1983).

Comprehensive Measures of Particular Interpersonal Stressors

To assess multiple aspects of a specific stressor (e.g. caregiver stress), comprehensive, domain-specific measures are available. Pearlin et al. (1990) has developed reliable and comprehensive measures of

family conflict related to caring for a loved one with Alzheimer's disease. These measures assess background and context variables, primary and secondary stressors, social support and coping mediator variables, secondary intrapsychic strain, and multiple outcomes as well as family disagreement about issues of safety, affection and appreciation. Similarly, Parris-Stephens and colleagues (2001) used reliable measures to assess instrumental stress (stress related to helping with transportation, shopping etc.), behavioural stress (stress related to dealing with a parent's emotional and memory problems and agitation etc.), and interrole conflict (not enough time/energy, too many demands). See Table 1 for alphas on these two measures.

Global Measures of Chronic Negative Social Interactions

There are several issues to be considered in assessing the effects of chronic negative social interactions on health and well-being. Although not framed explicitly as chronic stress in the literature, many investigators are studying the impact of negative social relations which are often chronic in nature. Several investigators use global, source-specific measures to focus on specific aspects of social relations and these studies make important and unique contributions. Some focus on both positive and negative aspects of support (e.g. Antonucci, Lansford, & Akiyama, 2001; Reinhardt, 2001; Rook, 2001) as well as the source

Table 1. Key/illustrative measures

Authors	Measure	Item description	Use
Antonucci, Lansford & Akiyama (2001)	Negative and positive social relations	Example item: 'My friend/spouse gets on my nerves.'	Quick and easy to administer Global measure
Brown & Harris (1989)	Life events and difficulty schedule	Interviewer's contextual ratings of chronic stressors (e.g. work)	Part of multidimensional assessment of stressors: severe events, financial hardship, work experience, childhood adversity
Cohen et al. (1983)	Perceived social stress	Example items: 'How often have you felt nervous and stressed?' $\alpha = 0.84$ to 0.86	Global stress measure Quick and easy to administer
Derogatis & Fleming (1997)	Derogatis stress profile	Environment $\alpha = 0.85$ Personality mediators $\alpha = 0.88$ Emotional response $\alpha = 0.83$	Multidimensional measure Assesses outcome
Moos & Moos (1997)	Life stressors and social resources inventory	Physical, housing, finances, work and relationships αs range from 0.79–0.84	Multidimensional measure Adult and youth forms
Parris-Stephens, Townsend, Martire & Druley (2001)	Parent care stress	Instrumental stress $\alpha = 0.79$ Behavioural stress $\alpha = 0.74$ Interrole conflict $\alpha = 0.74$	Multidimensional measure of parent care stress and role conflict
Pearlin et al. (1990)	Family conflict	Issues of seriousness/safety of loved one $\alpha = 0.80$ Attitudes and actions toward patient $\alpha = 0.86$ Attitudes and actions toward caregiver $\alpha = 0.84$	Comprehensive measure of family conflict
Rook (2001)	Daily social exchanges – positive and negative	Example items: Asked if someone 'Made them angry', 'Hurt their feelings' $\alpha = 0.81$ aggregated over 14 days	Daily diary study – difficult and time consuming but can assess chronic stress on daily basis
Turner, Wheaton & Lloyd (1995)	Chronic stress	Example items: 'You want to change jobs but don't think you can.'	Multidimensional measure

of support (such as spouse, children, friend) (e.g. Antonucci, Lansford & Akiyama, 2001; Reinhardt, 2001). Reinhardt (2001) assessed positive and negative support *provided* and *received* thus illustrating another facet of measuring social relations. Furthermore, sociodemographic characteristics including age, culture and gender influence positive and negative social relations. See Table 1 for examples of these kinds of measures.

FUTURE PERSPECTIVES AND CONCLUSIONS

Research thus far indicates that stress is fundamentally affected by individual and environmental issues and needs to be considered within a lifespan perspective. While recent evidence makes it increasingly clear that longitudinal research is critical, also important is the use of multiple assessment methods ranging from detailed qualitative interviews of special populations to quantitative assessments based on representative samples.

Lepore (1995) suggests the use of naturalistic observation, informant-based observations and laboratory analogues of conflict. It might be informative to combine several measures including self-report. The daily diary approach offers an interesting way to capture the chronicity of negative stressful relations, as well as other stressors. Participants typically complete a daily checklist to assess positive and negative stressful social exchanges (e.g. Rook, 2001). Alternatively, qualitative studies offer rich information about the history of stressful relationships among adult children and their parents.

Wheaton (1994) suggests measuring several types of stress such as chronic stressors, life events, and daily hassles. This strategy will allow for a more complete assessment of stress as well as the independent or interactive effects of stress on well-being. Similarly, Thoits (1995) suggests that instead of debating the value of measuring life events versus chronic stress, it may be useful to examine event/strain sequences and how they work together to influence well-being.

Lepore (1995) points to two technical challenges in stress research. First, the need to disentangle subjective and objective stress measures. There is a tendency to rely on self-report measures of stress and conceptualize the same measure as both objective and subjective. Second, it is critical to assess the duration and onset of chronic stress which is not an easy task. Illness duration is especially important in relation to health outcomes; however, it is often neglected in research. The chronic nature of the stressors discussed above has the potential to lead to poor psychological and physical health. However, most studies assume chronicity without actually assessing duration and onset of social stress (Pearlin, 1989; Lepore, 1995). Due to the ambiguous nature of social stress it is difficult to determine when it began. However, it is important to measure onset and duration to truly understand the relationship between chronic stress and physical and psychological health over time (Lepore, 1995).

Thoits (1995) provides several suggestions for future research. First, much stress research focuses on psychological well-being while assuming the results apply to physical health outcomes as well. Research needs to focus on which types of stress are related to which outcomes. A second area that needs further exploration involves the carry-over effects of stress across individuals, roles, and stages of life. Does work stress carry over to affect one's spouse? Does stress from childhood have important implications for well-being in adulthood? Finally, most research assumes that stress is inherently negative. However, stress may be harmful to well-being in the short-term but valuable in the long-term.

SUBJECTIVE METHODS

INTRODUCTION

The term subjective methods refers to a series of methods aimed to assess the psychological structure, content, and processes of individuals' subjective views, or personal meanings, about themselves and the world. These methods have been created and used by researchers more interested in the personal constructions of subjects than in classifying or locating them along theoretically pre-established dimensions or constructs (e.g. extraversion, locus of control). Typically, subjective methods are employed within orientations that place an emphasis on

the subject's personal constructions such as constructivist (Neimeyer, 1993; see entry on 'Theoretical Perspective: Constructivism'), hermeneutic, and narrative approaches. In this entry we will briefly describe the Repertory Grid Technique (RGT), the semantic differential, and provide a broad perspective on adjective lists, narrative methods and hermeneutics, although we recognize that, in their practice, psychologists have used a wider array of other less structured subjective methods.

REPERTORY GRID TECHNIQUE (RGT)

In the context of his 'Personal Construct Theory' (see entry on 'Personal Constructs'), George Kelly (1955) created the Role Construct Repertory Test, or reptest, and also its grid form. Since then, it has evolved not as a test but as a methodology known as RGT (for a review see Feixas & Cornejo, 1996; Fransella & Bannister, 1977; Rivas & Marco, 1985) with a variety of formats and applications which not only assess various issues in clinical psychology but also cover vocational assessment, education, business practice/management, and other more remote areas such as landscape appreciation and the study of urban tribes or anthropological investigation of folk beliefs of primitive tribes, with more than 2000 publications (Neimeyer, Baker & Neimeyer, 1990).

Defined broadly as 'any form of sorting task which allows for the assessment of relationships between constructs and which yields this primary data in matrix form' (Bannister & Mair, 1968: 136), the RGT assesses the dimensions and structure of personal meaning, usually in the subject's own terms. Thus, it aims at grasping the way an individual (although it has also been applied to the study of groups and institutions) makes sense of him or herself and others. The RGT explores the structure and content of the construct systems, implicit theories or meaning structures with which people construct their experience, perceive and act.

The administration of the RGT involves four stages (Feixas & Cornejo, 1996) in the context of a structured interview. First, a grid format must be adapted to the specific aims of the assessment as applied to a particular subject or group. Second, a set of usually 10–20 elements must be selected from the subject's world. Often, these elements represent various 'role titles' of significant others (heading columns in the example shown in Table 1) who play a part in the person's life (e.g. family members, employer, friends, a disliked figure) including his or her present self and the ideal self. However, a wide array of phenomena have been used as elements, including parts of one's body, self-roles, countries, occupations, and situations involving death and dying. Third, in order to elicit the constructs (which will be written in the rows, as in Table 1) the individual is asked to concentrate on pre-selected groupings of two or three elements and to construe them in terms of their similarities and/or contrasts, which requires the subject to provide the meaning dimensions that make these elements similar or different. In so doing, this interview elicits the personal templates by means of which the person interprets that particular domain of her or his experience. In the fourth stage, usually employing a rating system (Likert-type scale), the subject is required to allocate the remaining elements to the elicited constructs which takes a grid form with the elements as columns and the constructs as rows. Thus, by applying (rating) all the constructs across the entire set of elements a grid data matrix is created (see Table 1). This matrix can be analysed in a variety of ways ranging from qualitative appreciation of the nature and quality of the constructs used to the statistical analysis of the data using cluster analysis or factor analytic methods. Finally, a number of cognitive measures can be extracted (differentiation, cognitive complexity, self-esteem, conflict analysis, extremity of ratings, etc.) which can serve both to generate clinical hypotheses and to look for individual differences.

SEMANTIC DIFFERENTIAL (SD)

This instrument was created in the context of Osgood's (e.g. Osgood, Suci & Tannenbaum, 1957) mediation theory. According to this, 'words represent things because they produce in human organisms some replica of the actual behaviour towards these things, as a mediation process' (p. 7). To study the structure of meaning Osgood and his colleagues carried out a series of experiments which were to be the basis of the SD. A large number of subjects were provided with lists of, for example, 50 adjectives randomly

Table 1. An example of a client's repertory grid (translated from Feixas & Cornejo, 1996)

Date : Jan. 4th. 1990. Name: Daniel X.		1 Self now	2 Mother	3 Father	4 Brother	5 Sister	6 Spouse	7 Grandmother	8 Male friend	9 Female friend	10 Non-Grata	11 Therapist	12 Self before problems	13 Ideal self

chosen from a thesaurus in the form of 7-point scales (e.g. rough–smooth). On each of these scales, subjects were asked to rate a number of concepts (such as boulder, father, sin, Russian, me, etc.). These procedures produced large amounts of data that were factor analysed, which in different studies tended to yield what was called an *evaluative* factor, which usually accounted for 35% of the total variance. A second factor that emerged was termed *potency*, and the third one, *activity*. These were assumed to be the basic dimensions of meaning, defined as a semantic space in terms of which an individual could plot a particular concept.

For application to an individual case, the usual procedure is to select a number of scales which previous studies have shown to be relevant for the purpose of the study, and to ask the subject to apply them to a set of selected concepts representing the topic of the study. The SD offers then the opportunity for cross-comparison of the meanings of two different words for one subject, or the meanings of the same word for a number of subjects, by enabling the experimenter to sum ratings in terms of three allegedly major dimensions of meaning.

ADJECTIVE LISTS (AL)

As in the above methods, this heading does not refer to one single instrument but encompasses a variety of procedures that have in common the presentation to the subject of a list of adjectives for application to her or himself or to others using a given rating scale. ALs can be constructed for a specific case in a particular situation according to the purpose of the assessment; however, with time more and more standardized lists have appeared. Some are suggested for use as instruments to assess a particular condition (e.g. depression) while others have been used since the 1940s (Allport, Cattell) as a method for the study of personality. The idea of using ordinary language for the study of personality is based on the so-called 'lexical assumption' according to which the ideas or individual differences which people consider important will eventually become encoded into words.

One of the most used ALs is Wiggins' (1995) Interpersonal Adjective Scales which measures Dominance and Nurturance, which are viewed as important dimensions of interpersonal behaviour. Respondents rate themselves on a list of 64 pre-established adjectives using a 8-point Likert scale according to how each adjective best describes them.

NARRATIVES AND HERMENEUTICS

The use of narrative texts has been proposed as a complement to traditional methods of psychological assessment and, in some cases, as an alternative. Allport (1942) was perhaps the first to call attention to the psychological value of texts such as diaries, letters, memoirs, and life stories (interview transcripts might also be added to the list). But it has not been until the last two decades of the 20th century that the use of narratives has acquired prominence. Its psychological value is based on the hypothesis, maintained by Bruner (e.g. 1991), and other authors such as Howard, Mitchell, Polkinghorne, and Sarbin, that construction of experience is of a narrative nature.

Narratives have been used as a means for assessment not only in psychology but also in sociology, education, and anthropology, as well as medicine for diagnosis, to evaluate issues of gender, race, religion, social class, etc., and also aspects related to development in infancy, adolescence, and old age. Narratives have become particularly relevant in psychotherapy after the work of White and Epston (1990).

Work with narratives has a hermeneutic character, since these texts must be considered themselves a hermeneutic product or construction. Many studies have directed their attention to the structure or the content of narratives. Thus, a possible focus would be centred on the study of the script (plot analysis), each story following a progressive, regressive, or stable line. The protagonist, appearing as a victim or a hero, can also be the object of the analysis. The story can be considered fragmented or coherent, open or closed. In any case all stories follow a narrative scheme that obeys the invariable structure of narrative grammar, constituted by a context, a beginning, movement leading towards an established goal, an outcome, and an ending.

A distinctive perspective can focus on the categories of the contents, applying, for example, attribution styles (internalization, stability,

globality) to the narrated episodes. In turn, Angus and Hardtke's (1994) coding system provides three codes for processing narratives: external, which supposes/consists of a description of events, internal, which refers to subjective experiences, and reflexive, which involves analysis of those experiences. Another system is that of McAdams (1993) who proposes the categories of communion (love/friendship, dialogue, care/help, and community) and agency (self-mastery, status, achievement, and empowerment). The researcher may either use these or other existing categories or employ *Grounded Theory* as the frame to derive categories directly from the text.

Some authors, however, believe that the models described thus far do not respect the 'autonomy of the text', in that for their analysis they introduce external categories, or fragment or isolate the text from the context in which it was produced. For example, Villegas (1993) postulates a textual hermeneutics on the basis of linguistic concepts, such as text and context, coherence, relevance, macrostructures, and macropropositions. Utilizing these concepts, he attempts to extract from the text's own structure the hermeneutic keys for its interpretation, paying more attention to the discursive aspects of the text.

FUTURE PERSPECTIVES

Subjective methods, in comparison to traditional approaches to psychological assessment, have always had a marginal impact on mainstream psychological practice. Recently, however, with the increase in theoretical interest in postmodern thinking, complexity, and constructivism (and some dissatisfaction with conventional assessment approaches), subjective methods may find their way in the psychological arena. Particularly, in the area of psychotherapy (e.g. Feixas & Villegas, 2000), these approaches are becoming more influential, probably because more traditional, often simplistic, models do not deal adequately with the complexity encountered in clinical practice.

The future might provide varying perspectives for the different methodologies described. With respect to the RGT, its use has already been quite extensive in terms of the number of studies and the topics covered but its impact as an assessment tool of choice among practitioners is still limited. The proliferation that has occurred in the last 15 years of computer programs for both the administration and analysis of repertory grids may prelude a substantial growth both in psychological practice and research. In particular, the availability of information through various university based websites (e.g. www.ub.es/personal/pcp.htm or www.med.uni-giessen.de/psychol/pcpmain.htm), and even the possibility to access these computer programs through the Internet (www.repgrid.com or www.terapia-cognitiva.net), might facilitate the dissemination of this approach. In any case, we can count among the major potential drawbacks of RGT its complexity and its mainly idiographic focus (see entry 'idiographic methods') – precisely (and paradoxically) those aspects which constitute also its strength. RGT is not a quick and ready-to-use instrument, rather it needs to be adapted to the assessment purposes for which it is to be used. The data analysis (involving some interpretation of statistical analysis) is not a simple task either. For this reason, some training is required in order to develop the necessary skills to apply the RGT with a certain degree of success. Finally, the preference of RGT for using the subject's constructs and for adjusting the grid format to the individual makes the generalizability of the results a complex task. In sum, RGT accumulates a number of substantial advantages for those seeking a systematic instrument to investigate the structure of personal meanings provided that they want to take the effort to study with detail the issues regarding administration and analysis, and the theoretical context in which it is embedded.

The SD has received a certain amount of attention in the field of social and personality psychology. The possibility of selecting a set of scales to evaluate some target concepts make this instrument a reasonable choice for investigating a variety of research topics. In the past we have not witnessed, however, an increase in the number of studies using SD. Reasons for this can be found in the absence of theory development related to the instrument, or the little interest that it has provoked in applied contexts (either clinical or educational). SD appears to be half-way between entirely idiographic and traditional methods. Maybe we can attribute to this characteristic the present situation and future perspective of this technique.

With respect to AL, a continuously growing trend can be identified in the existing literature. Starting with the industrious studies involving hundreds of adjectives with large samples, the use of AL has evolved via a series of instruments for assessing personality-related and clinical issues. In all likelihood, these two areas represent the more promising perspectives for this approach. In the area of personality assessment, ALs have been part of the development of the big five factorial and the interpersonal circumplex models (see De Raad, 1999); developments that can be located within the mainstream lines of this area. In the clinical context, a number of specific ALs have appeared and are being used for research and practical purposes in areas of enormous relevance such as depression, and personality disorders. As said, all these developments provide the basis for the prospect of substantial growth of AL-based instruments in the future of personality and clinical psychology.

Finally, as suggested, hermeneutic and narrative methods grew out of a long tradition in psychology and, at the same time, are gaining more and more interest not only in psychology but also in other disciplines. Probably these methods will gain momentum when implemented in conjunction with computer programs that facilitate and normalize the tasks involved in performing such analyses. In fact, nowadays this is beginning to happen already with software such as *Nudist* or *Atlas-TI* designed to analyse texts. Perhaps, among the major disadvantages of these methods, we can count its great diversity and the amount of work in detail required to work with narratives.

CONCLUSIONS

Subjective methods, and the theories from which they derive, have always been a marginal trend in psychology, in a broad sense, and in psychological assessment, in particular. However, this has not led them to 'extinction' but rather to an impressive development across the years in a variety of different directions. These varied groups of techniques have informed theoretical issues in personality as well as applied ones in psychological practice (assessment and psychotherapy). In fact, the range of application of these methods is so broad (as with, e.g., narrative methods) that they have been used by other disciplines. Perhaps the diversity of existing subjective methods might be its central, more distinctive quality. One of the dimensions along which we can plot the different approaches to psychological assessment covered in this entry is related to the degree the researcher uses the subject's own constructions or wordings (as in RGT and narrative/hermeneutic methods) or rather asks the subject to rate him or herself in pre-established categories (as in AL and SD). We can also find intermediate solutions to this question when looking at particular procedures.

In sum, in this variety lies the richness and the major difficulties of subjective methods. The degree to which psychology practitioners will be able to deal with this complexity will determine the value and the future of these methods.

SUBSTANCE ABUSE

INTRODUCTION

Substance abuse is not only a behaviour referring to the occurrence and/or frequency of drug use, but it also supposes a particular lifestyle. Drug use, which may or may not lead over time to abuse, is one more behaviour of the many carried on by an individual in the process of adaptation to the environment in which he or she lives. It does not necessarily have to mean a change in lifestyle; it may affect just one specific area and be limited to that. On the other hand, development of an addiction is associated with a radical change in the individual, which is far greater in the case of illegal substances. An evaluation of addiction must also involve an assessment of all the variables potentially involved in the development of the addiction. Addiction appears to be an interactive product of social learning in a situation involving physiological events: both the social and psychological factors, and the physiological elements are indispensable features of the total experience and process of addiction. In this entry, we will refer in general to the assessment of consumption of illegal drugs, in the belief that all the variables evaluated in legal drug use are included here (Table 1).

THE EVALUATION PROCESS

An approach like this involves the use of multiple assessment procedures and a focus on multiple target behaviours. This means that we have to know the topography and functionality of self-administration of a psychoactive substance, and all the behaviours which are included in this lifestyle, as well as the areas which have been affected and the aspects of the context and of the subject which may have effect or be affected, in order to decide whether they are or are not problem behaviours, the variables to be modified or the points of support or of departure in the rehabilitation process. The characteristics of the

		Hallucinogenics
		Chemical products and precursors
		Others

substance are important in trying to explain the addiction to consumption of that product (whether tobacco, alcohol, opiates, designer drugs or any other), but there are other variables which are just as important in the explanation of the addiction, such as basic repertoires of behaviour of the individual, the learning history, or the risk variables of the context. In short, the evaluation process, to be implemented, must have an integrating effect and make possible the use of a variety of sources and techniques which allow its reliability to be enhanced. In this sense, account is not only taken of information provided by the consumer, by also that from family members and peers. The aim of the assessment must be to decide on the functional relations in place between the different variables involved (of the behaviour, the subject and the context), so as to design the most appropriate intervention procedure for the particular case. Functional analysis allows the following:

- Detection of the problem behaviours.
- Knowledge of the function variables making up the interaction.
- The other variables, not part of the interaction or specific to it; they are, rather, facilitating variables as much of the individual as of the surroundings, and affecting the likelihood that the interaction will happen.
- Design of a specific intervention for each individual; to establish targets: to choose the most suitable device; to decide whether support resources are needed; to select the therapeutic programmes; and to determine the specific intervention techniques.

Addictive conduct is highly complex and requires multiple interventions from a number of standpoints, depending on the aim of the intervention to be carried out, and the timing (e.g. a drug-free programme or a damage-limitation programme). The decision-making assessment for this decision is different, as is the weighting of the variables: this means that if a decision is to be made as to the most suitable detoxification procedure, biological and social variables will have greater weight. However, it will be particularly the biological and social variables which will decide on the treatment procedure and the specific intervention programmes in the phase for escape from the habit.

In an initial detoxification phase, there must above all be an evaluation (apart of course from the essential medical assessment) of the self-control skills, including previous attempts at detoxification (how many, when, the procedure, result, etc.), the information the subject has on withdrawal symptoms and the detoxification process, and the fears and skills for confronting it.

Once detoxification has been achieved, the assessment follows for the design of the treatment. Separate consideration will be given to the topographic analysis of consumption behaviours and its functional analysis, as shown in Figure 1.

INSTRUMENTS AND TECHNIQUES OF ASSESSMENT

The most-utilized assessment techniques and tools are the interview, observation, self-reports and self-registers, peer registers and reports, and physiological records and biochemical analyses. Most of the tools used in the evaluation of drug use have not been scaled: they have been developed and used for specific samples, making it difficult to compare and generalize results (except with reference to medical analyses and tests). We also consider it necessary to make a clarification concerning the aims of some drug-dependence assessment tools: since 1977, the WHO has proposed the so-called 'bi-axial concept' of addiction, whereby a distinction has to be made between what is referred to as the 'substance-dependence syndrome' and the problems related with consumption. The dependence syndrome is made up of a set of symptoms making up a common psycho-biological process forming the theoretical basis for current DSM and CIE nosological criteria. For their part, the problems related with drug consumption refer to the bio-mental-social deterioration associated with the use of substances, separating them from the nosological entity of 'dependence'. The tools for the assessment of each of these two aspects differ, as will be shown below. At all events, we cannot ignore the fact that the purpose of psychological assessment must always be a functional analysis of the specific case, irrespective of whether it is in line with a particular diagnostic classification, or the problems go beyond the pure consumption of drugs.

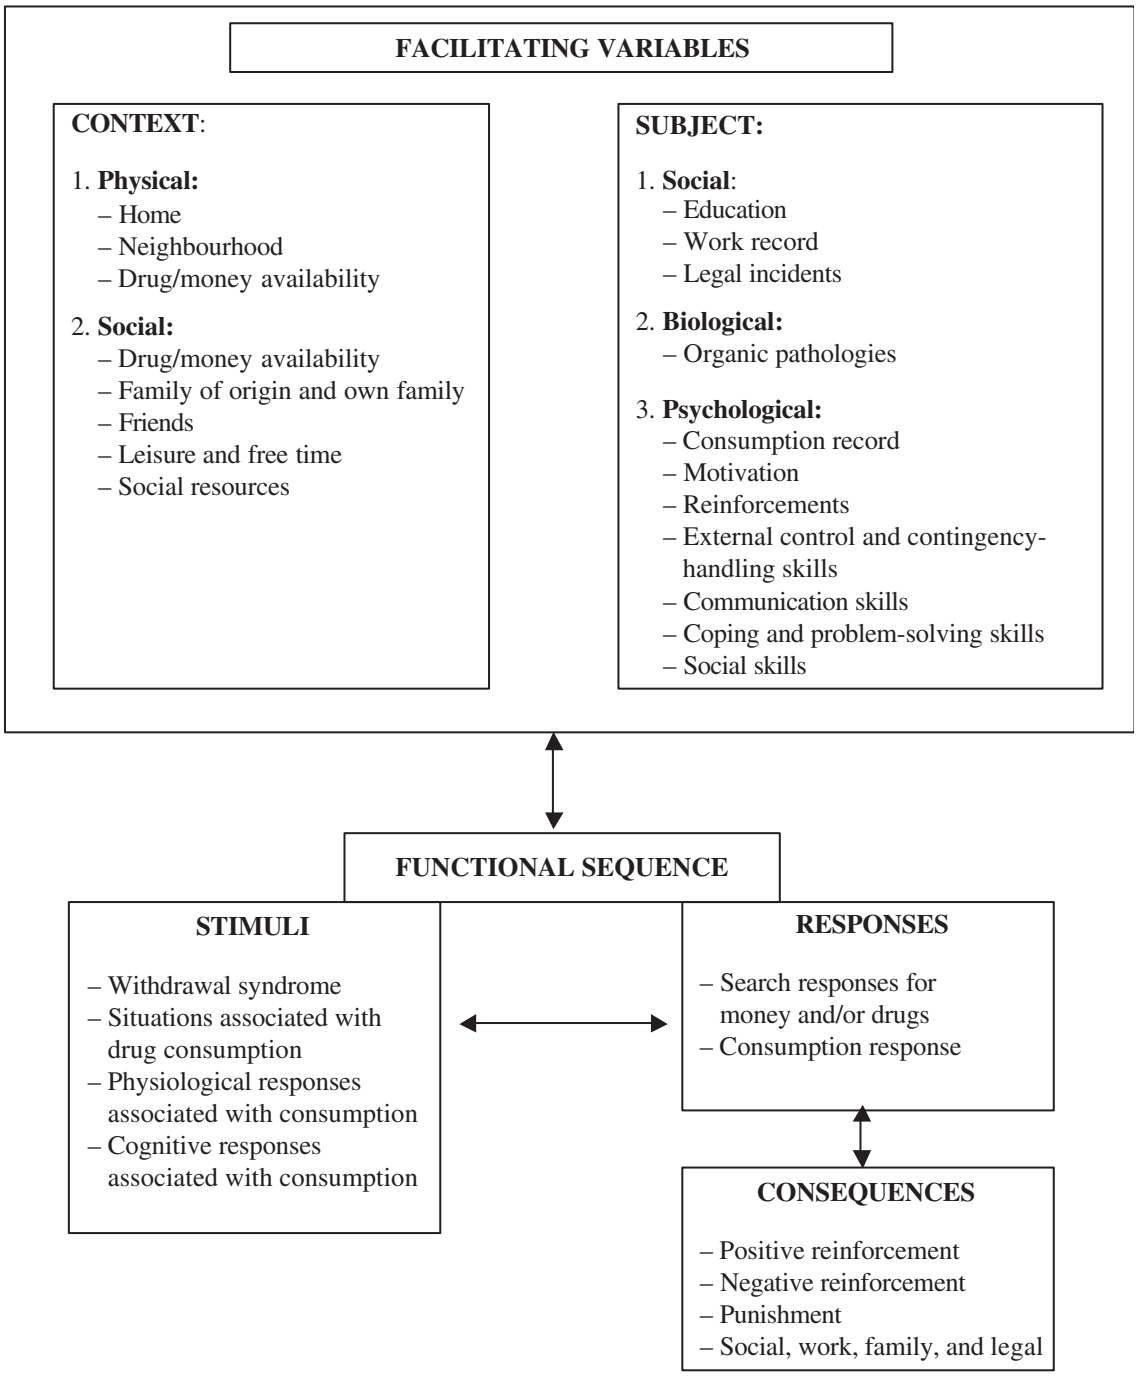

Figure 1. Functional analysis of drug-consumption behaviour.

A psychologist is interested in explaining why that consumption behaviour occurs in that particular individual, and then to use this explanation in the design of the specific treatment which will make it possible to modify the variables underpinning the problem in question. We will examine some of the current most-used tools, which are summarized in Table 2.

Table 2. Specific addictive behaviour assessment tools

Interviews		Self-reports	Physiological records and biochemical analyses
Assessment of the degree of dependence • CIDI-SAM (Cottler et al., 1989) • SCDI (Spitzer et al., 1990) • SCAN (Wing et al., 1990)	Assessment of consumption-related problems • ASI (McLellan et al., 1992) • OTI (Darke et al., 1992)	• SDS (Gossop et al., 1995) • SODQ (Sutherland et al., 1986, 1988) • CCQ (Tiffany et al., 1993)	• Urine analysis • Serological analysis • Toxicological analysis

Interviews

Most interviews used in drug-consumption assessment follow a semi-structured format aimed at securing data on virtually all the variables involved in drug-consumption: consumption record, previous abstinence attempts and periods, the motivation for the change, self-control, leisure and free time, social skills, etc. Interviews which assess dependency DSM-IV, according to the CIE-10, are the *Composite International Diagnostic Interview – Substance Abuse Module* (CIDI-SAM, Cottler et al., 1989), the *Structured Clinical Interview for DSM-III-R* (SCDI, Spitzer et al., 1990) and *Schedules for Clinical Assessment in Neuropsychiatry* (SCAN, Wing et al., 1990). Such interviews are aimed at evaluating all symptoms defining the dependence diagnosis, and they are the reference tool in research projects using APA or WHO criteria. On the other hand, the *Addiction Severity Index* (ASI, McLellan et al., 1992) is a semi-structured interview designed to evaluate consumption-related problems; in each area assessed, the interviewer establishes a severity index between 0 (the absence of a real problem, suggesting no need for treatment) and 9 (extreme likelihood, treatment absolutely essential). An adaptation has been developed for the European situation (*Addiction Severity Index – EuropAsi*, Kokkevi & Hartgers, 1995), which is currently being validated in a number of countries in the community. A similar line is followed in the *Opiate Treatment Index* (OTI, Darke et al., 1992).

Self-Reports

In addition to the usual self-reports assessing the psychological variables involved in the addiction process, and which are summarized in the corresponding sections of this project (personality variables, anxiety, social skills, self-efficiency, etc.), there are some tools specifically designed to evaluate consumption behaviour. Some seek to assess dependence both in terms of category (presence or absence) and of scale (seriousness), irrespective of the inclusion of all the elements of diagnosis or the definition of a notion of dependence other than those established by the most accepted criteria. One is the Severity Dependence Scale (SDS, Gossop et al., 1995); it consists of five questions with Likert type answers, giving a total score of the sum of each item. This scale has been the subject of an internal consistency analysis, an analysis of the main components and the correlation of some consumption variables, in a sample of heroin- and amphetamine-dependent subjects. Another commonly used tool is the Severity of Opiate Dependence Questionnaire (SODQ, Sutherland et al., 1986, 1988), which is almost exclusively aimed at evaluating withdrawal syndrome and tolerance. For its part, the Cocaine Craving Questionnaire (CCQ, Tiffany et al., 1993) seeks a multidimensional assessment of the craving for cocaine, in two versions: *Now* (immediate craving) and *General* (craving during the last week).

Physiological Records and Biochemical Analyses

While not psychological tests, they are also fundamental to the performance of functional analysis. There are a large number of tests which drug-dependent subjects must complete prior to the onset of any treatment (NIDA, 1986); urine

analysis (costly, like the radio-immune test – RIA – or gas chromatography/mass spectrometry (CS-SM), or low-cost such as fine layer chromatography or the immune-enzymatic test), serological analysis, and toxicological analysis (including immunological, spectrophotometric and chromatographic procedures) are all designed to evaluate the individual's general state of health, the presence of all forms of organic pathologies, and the actual consumption behaviour, by analysis of the metabolites the substance leaves in the body. In this sense, it is a standard practice that the information given by the individual or by peers on the consumption behaviour is compared with the results of the analyses, making it possible to identify precisely the presence or otherwise of the consumption of a variety of substances.

FUTURE PERSPECTIVES

The development of the psychological assessment of addictive behaviour is very slow, and is conditioned by the difficulties inherent to such conduct (confusion about the models for the genesis and maintenance of drug consumption, the illegal nature of the conduct, penalization of the individual if undergoing treatment and he or she consumes drugs, etc.). In recent years, there has been almost no alteration to the assessment process used in drug-consumption, nor in the techniques applied. With the progressive introduction of damage-limitation programmes (methadone or naltrexone maintenance, etc.) which have gradually replaced drug-free schemes, the main advances in assessment have been in urine-detection tests for the presence of methadone and other drugs, and we believe that it is in this area where the most significant advances will take place.

Another developing line refers to the evaluation of so-called *Personality Disorders* and their influence on the treatment of addictive behaviour. While this category is more than questionable as such, it is true that recent years have seen a sharp trend in the assessment and treatment of addiction behaviour aimed at examining the comorbidity between substance abuse and personality disorders, and their possible repercussions in the development and the results of intervention. Along these lines, the use is becoming established of the International Personality Disorders Examination (IPDE, Loranger et al., 1994) to identify relevant behaviours for the assessment of the various personality disorders according to DSM-IV and/or CIE-10 criteria, and their connection with addictive conduct. This tool is the result of the efforts of the World Health Organization (WHO) and Alcohol, Drug Abuse and Mental Health Administration (ADAMHA) to create universally applicable standardized assessment instruments.

CONCLUSIONS

The assessment of addictive behaviour is a very complex matter, not just because of the large number of variables involved defining a complete consumer lifestyle, but because of the features of the behaviour as such; drug consumption is illegal and so its assessment confronts difficulties outside the strictly psychological and/or technical realms. As with any other behavioural problem, the ultimate aim of assessment must be the functional analysis allowing the problem in question to be explained. There must be assessment of the variables of the subject, the behaviour and the context, not just those which may be considered to facilitate the conduction, but also those making up the functional sequence. The elements used in the evaluation of the variables other than consumption itself are those which are habitual in the psychological assessment of any problem: the specific means of consumption are characterized by the fact that they have been developed and used for specific samples, making comparison and the generalization of results difficult (except in respect of medical analyses and tests). Apart from psychological assessment, medical-biological evaluation is essential in the problems of addiction in order to identify possible organic pathologies, and for the detection of metabolites of the substances consumed.

TEMPERAMENT

INTRODUCTION

Most researchers in the domain of temperament agree that temperament refers to basic, relatively stable, personality traits present from early childhood and they have their counterpart in animals. There is, however, no consensus about such issues as the biological bases of temperament, the quality and number of traits of which the structure of temperament is composed, and hence there does not exist a commonly accepted view on how to measure temperament, and what has to be measured (see Strelau, 1998; Teglasi, 1998). Whatever the difference between researchers on temperament, three methods have been applied in assessing this phenomenon: observation, interview, and questionnaires (inventories), whereby the latter gained the highest popularity.

ASSESSMENT OF TEMPERAMENT BASED ON OBSERVATIONAL DATA

One of the methods for assessing temperament, applied mainly to infants and children not exceeding kindergarten age, is observation of behaviour in natural settings, of which the home environment is most typical (e.g. Ricciuti & Breitmayer, 1988). Home observations are based on the assumption that home is the most natural and influential environment for children until they reach school age. Parent–child interactions, with the distinctive role of the mother, are essential for the behavioural expression of the child's temperament and for the way it is perceived by parents.

Depending on the goal of the study home observation procedures differed. Several studies have shown high inter-rater agreement depending on the kind of behaviour being assessed. On the average, inter-rater agreement of temperament characteristics based on home observation is about 0.80 (Frankel & Bates, 1990). Intersession stability, as well as split-half reliability of temperament measures based on observational data, was usually much lower, probably not exceeding on average scores between 0.20–0.30 (Ricciuti & Breitmayer, 1988; Rothbart, 1986).

The fact that home observation is conducted under the most natural environment has its price, mainly in lack of or little control of the situation in which children's behaviour is recorded. Coding behaviour is imprecise, and biased by the observer's limited capacity to grasp the whole range of relevant behaviour (see Rothbart & Goldsmith, 1985).

Observation under laboratory conditions that allow for control not only of behaviour but also of the specific stimuli and situations expected to provoke behaviour in which temperamental characteristics reveal themselves has recently gained considerable popularity among child-oriented temperament researchers.

In laboratory assessment of temperament, different episodes are arranged depending on child age and specific goal of the study. These

episodes are often divided into smaller units during which infant responses (e.g. smiling, crying) are recorded. The assessment procedure is conducted in a typical developmental research laboratory with standard settings and equipment (see Kagan, 1994; Matheny, 1991).

Observation in the laboratory setting has also several shortcomings (see Rothbart & Goldsmith, 1985). For the child, a laboratory setting is a new environment that may evoke avoidance behaviour or inhibit typical reactions. Some parents are reluctant to agree to laboratory assessment, which results in selected samples of children for study.

Observational methods, whether at home or in the laboratory, are based on the premise that temperamental characteristics are revealed in behaviour typical for natural or semi-natural settings. This assumption is only partially satisfied because behavioural observation is biased by so-called reactivity effects which occur when the observing process alters the behaviour of individuals observed. Observation is a time-consuming procedure, requires individual contacts between observer and observant. The variety of behaviours available for assessment during observation is very limited. Reliability estimation can be properly done only when more than one observer takes part in the assessment procedure (for details, see Rothbart & Goldsmith, 1985).

INTERVIEW AS A SOURCE OF INFORMATION REGARDING TEMPERAMENT

Interview, along with observation, has an old tradition in clinical practice. It is a method for collecting information about the patient's health status, well-being, family, environmental settings, etc. As distinct from observation, which permits only to recording overt behaviour, interview allows collection of information about covert (internal) reactions and states. Whether applied directly to individuals or to partners, parents, and teachers assessing others (mostly children), interview is always based on retrospective data which are essentially subjective.

Interview for diagnosis of temperament has been used in the first place by psychiatrists and paediatricians (Garrison, 1991). Interview questions, mostly face-to-face, are often unstructured. Even when structured and answered in terms of quantitative rating, they are destitute of psychometric properties typical for questionnaires.

In the domain of child temperament, Thomas and Chess (1977) introduced the interview method in the New York Longitudinal Study (NYLS) initiated in 1956. Interviews may be regarded as an important source of information about temperament characteristics when personal contact with individuals (patients, parents, teachers) is possible. Structured questions about temperament and parental perceptions in the face-to-face interview allow for more in-depth probing of responses and the elicitation of information not captured through paper-and-pencil techniques alone (Garrison, 1991).

Because this procedure requires much time from the interviewer, the number of interviewed persons is, as a rule, rather small. Questions formulated during interviews often served as the basis for generating questionnaire items, as was the case in the Thomas and Chess (1977) NYLS project.

TEMPERAMENT QUESTIONNAIRES

The questionnaire method used for assessing children's temperament is based on retrospections given by parents, other caretakers, and teachers. In the case of adolescents and adults, questionnaires refer to self-report, although rating by others (partners, peers) gained popularity. Taking the 'who' criterion as point of departure, issues relating to questionnaire assessment of children's and adult's temperament will be presented separately.

Questionnaire Approach to the Study of Temperament in Infants and Children

The number of inventories for diagnosing infant and children temperament has grown, a complete record of which would probably extend to over half a hundred. Hubert, Wachs, Peters-Martin, and Gandour (1982), in their analysis of the psychometric properties of temperament instruments designed for infants and children, listed 26 such instruments. A review made 9 years later (Slabach et al., 1991) added 7 new questionnaires. Table 1

presents an updated review of temperament inventories most often used in recent studies separately on infants and children, and on adolescents and adults (see also Teglasi, 1998). The list comprises exclusively those inventories constructed for English-language populations.

The inventories presented in Table 1 illustrate the diversity of approaches in the construction of questionnaires in terms of such criteria as theory underlying the instrument, population of respondents being addressed, age of infants and children for whom these instruments are designed, strategies utilized in constructing inventories, the answering format, and the number and kind of traits being measured.

Questionnaires designed for parents refer mainly to child behaviour observable at home or in surroundings where parents are together with their child. To study the functional significance of children's temperament in kindergarten and school activity, inventories have been developed for teachers. They are composed of items which refer to behaviours observable in the school environment.

Two questions were critical in the discussion regarding assessment of children's temperament by raters, namely: (1) to what extent the assessment of a child's temperament depends on who is the rater: mother, father or teacher (interscorer reliability), and (2) what do we measure by means of inventories – the child's real temperament or the perception of temperament by mother, father, and teacher (validity issue).

Numerous studies have shown that the correlations between mother and father temperament ratings are only moderate, at best in the range between 0.40 and 0.60, depending on the scale taken into account (for a review, see Strelau, 1998).

Considering these moderate, or even less than moderate, correlations between mother–father ratings from a reliability perspective, presumably the same measure is not the same for mothers and fathers. There are several variables that contribute to the reliability of parents' temperament assessment (see Hubert et al., 1982; Slabach et al., 1991). For example, parents use different criteria in judging the inventory items, and to mother and father for whom different behaviours of the assessed infant and child are available, they ascribe different weights to different behaviours.

In some inventory studies, parent (mostly mother) rating was compared with teacher rating. Goldsmith and Rieser-Danner (1986) summarized correlations for mother and teacher agreement taking into account nine studies from the Austin Day Care Project, in which eight different temperament inventories were applied (IBQ, ITQ, ICQ, TTS, EASI-III, TBAQ, BSQ, and DOTS). The ranges of correlations between mother–teacher ratings varied from −0.49 to 0.55, with negative correlations representing the extreme scores in six studies, which questions the generalizability of temperament assessment.

The moderate agreement between parent ratings, and even poorer agreement between parent–teacher ratings, prompted researchers to ask whether the phenomenon to be measured can indeed be identified as children's temperament. Two most radical positions have been taken by Thomas and Chess (1977) and by Bates (1980). According to the first, inventories allow for measurement of real temperament modified by parents' attitudes and behaviour. In turn, Bates postulates that questionnaires measure only the perception of children's temperament by parents and other raters.

Several authors (e.g. Goldsmith & Rieser-Danner, 1990) postulate that assessment of temperament is an outcome of a variety of interactions between the assessed child and the rater, including the social context, the actual situation, accumulated experience, and the raters' own personality-temperament characteristics.

Slabach, Morrow and Wachs (1991) summarizing their review regarding reliability and validity data of infant and child temperament inventories arrived at several conclusions, some of which are worthy of mention. First, the 1991 review confirms that moderate internal consistency is the norm for most temperament inventories, with some scales from CCTI, MCTQ, IBQ, TBAQ, DOTS-R, TAB, and TTQ-S demonstrating levels of internal consistency higher than 0.80, or at least 0.75. By the way, the recently developed SATI shows reliabilities in the range of 0.85–0.90 (McClowry, 1995). Second, most temperament questionnaires for assessment of infants and children show, in general, satisfactory short test–retest reliability and moderate cross-time stability. Third, several instruments, for example TTQ-S, RITQ, IBQ, TTS, BSQ, show satisfactory external and/or convergent validity, measured by such criteria as behaviour disorders, behaviour in classroom, at home, and relationship with attachment.

Temperament Questionnaires for Adolescents and Adults

There exist several dozens of questionnaires in use in current studies for assessing temperament in adults (see Strelau, 1998). Table 1 presents selected questionnaires which are currently among the most popular.

Temperament questionnaires for adults are mainly based on self-rating, which is one of the features discriminating them from temperament inventories for children. One of the methods for validating temperament inventories in adult populations is the comparison of self-rating with peer-rating. This procedure is based on the assumption that the peer (a friend, partner, or family member) is well-acquainted with the subject, and has had opportunities to observe the subject's behaviour in different situations over time.

The richest evidence of self- and peer-rating comparisons in temperament characteristics has been collected by Angleitner, Strelau, and their coworkers in the Bielefeld–Warsaw Twin Project (BWTP). Data collected from over 3000 twins (one twin from each pair) and over 6000 peers (two peers for each twin) including German (G) and Polish (P) samples allow some general conclusions to be made. The PTS, FCB-TI, EAS-TS, DOTS-R, and EPQ-R inventories, including altogether 27 scales, show satisfactory averaged reliability scores for both self- and peer-report [self-report: 0.78 (G) and 0.74 (P); peer-report: 0.79 (G) and 0.77 (P)]. Agreement between self-report and peer-report was on the average: 0.48 (G) and 0.47 (P), and between raters: 0.55 (G) and 0.54 (P) (for a detailed description, see Strelau, 1998). Data from the BWTP suggest that self-report/peer-report agreement (not corrected for attenuation) is comparable with agreement between peers.

Strategies for Constructing Temperament Inventories

Taking a methodological perspective on temperament inventories for assessment of children and

adults reference can be made to three basic strategies used in constructing personality inventories: deductive strategy, inductive strategy, and external strategy (Burisch, 1986).

The majority of temperament inventories were constructed by using the deductive strategy. Temperament researchers, however, differing in their understanding of what temperament is, and the structure of which it is composed, took their conceptualizations with respect to these issues as a starting point for constructing questionnaires. Differences in construction strategies refer mainly to the psychometric and itemmetric advances. From this point of view, several categories of temperament inventories can be distinguished.

- Inventories developed on the basis of interview items which bring rather to mind a well-structured interview with scales corresponding with the theoretical concepts. Grouping items into scales was done arbitrarily, without any psychometric procedure to back it up (e.g. the PTQ and TTQ).
- Questionnaires in which theoretical constructs have been operationalized into scales composed of items having content validity, and internal consistency with the scale to which they have been ascribed. Most representative inventories are those developed within the Thomas–Chess tradition (BSQ, EITQ, MCTQ, RITQ, TTS). Other inventories based on different temperament theories may also be classified in this category; for example, IBQ, CBQ, STQ, PAD.
- Questionnaires that have been constructed by thorough psychometric analysis, including content validity, internal consistency, convergent and divergent validity and detailed itemmetric characteristics. The PTS, FCB-TI, TCQ and TBAQ are typical examples of this kind of construction strategy.
- Questionnaires based on theoretical constructs to which, by means of factor analytic procedures, scales have been developed mainly in the attempt to obtain as much orthogonality between scales as possible. This strategy focuses on scale construction with less attention to itemmetric analysis. Several temperament questionnaires have been constructed by use of this strategy, such as the EAS-TS, EPQ-R and SSS.

There exists a whole group of questionnaires (e.g. ICQ, DOTS-R, SITQ, SATI, TTQ-S, TAB, CCTI) which resulted from a mixture of the deductive and inductive strategies of scale construction. These are instruments for which the construction of items and/or scales of existing inventories were taken as a starting point, and which are composed of scales that are a result of different factor analytic procedures. Questionnaire constructors representing this approach arrived at different scale solutions, mostly (with the exception of DOTS-R) with a reduced number of scales as compared with the nine categories and nine scales proposed by Thomas–Chess.

Personality Assessment (General)

TEST ACCOMMODATIONS FOR DISABILITIES

INTRODUCTION

Access to educational opportunity or to the workplace often requires taking a standardized objective or performance test. For most people, taking on-demand exams present little difficulty, at least in terms of the form, structure, or procedures used by the test to assess the skill or learning construct. For individuals with disabilities, however, the structural characteristics of a test may present barriers that interfere with the assessment, yielding results that are inaccurate representations of what an individual knows or can do. For this reason, individuals with disabilities may take a test with an accommodation (i.e. adjustment) to the material used for the test, the procedure or procedures for administering the test, or to the way they respond. Accommodations are intended to remove or diminish the impact of the disability on test performance without invalidating the test construct or the score. Specifically, it is discriminatory to use selection criteria based on tests that screen out or tend to screen out individuals with disabilities unless the criteria are shown to be job-related, consistent with a business necessity, or related to a prescribed admissions standard. A test accommodation is called for when the test process or procedure requires an individual with a disability to use the impaired skill(s). Test accommodations are not testing modifications although the terms are often used interchangeably. Generally, an accommodation is considered a change in the way a test is administered but does not alter the construct and a modification is considered a change in the content of the test and may alter the intended construct.

With the onset of high stakes testing for school accountability purposes and access to post secondary institutions and eventually to employment opportunities accommodations have become commonplace when people with disabilities take on demand tests. Tests are not to act as barriers to the employment or admission to school of persons with disabilities unless the person is unable to do the job or be successful in school, even with reasonable accommodation.

CHARACTERISTICS OF TEST ACCOMMODATIONS

There is no approved set of assessment accommodations but most people agree that accommodations can be classified as adjustments to test setting, item presentation, time limits, response formats and test schedule. The most commonly used accommodations involve (1) changes in timing or scheduling, (2) special arrangements about where the test is taken, (3) allowing non-standard modes for responding, (4) Braille or large print, (5) reading questions or content aloud to a test taker, and (6) permitting individuals to engage test items using non-standard presentation formats (Thurlow, Scott & Ysseldyke, 1995). Much variability exists in how accommodations are employed as singular adjustments, or in combination, and research revealing their impact is just emerging. Indeed, accommodation research is difficult to design and perhaps even more difficult to interpret. Accommodations are designed to address individual needs so group data may be confounded by the complexities of interactions between subjects who may or may not need the particular accommodation(s) being tested.

PSYCHOMETRIC ISSUES AND ACCOMMODATIONS

Studies have analysed the effects of accommodations on test scores. For the most part, these studies have analysed large data sets collected from tests that use item formats that require examinees to 'select a response' in the form of multiple-choice or other objective items. Much less research has been completed using 'performance-based items', or items where examinees are asked to 'construct a response'. Clearly, accommodations allowed for one item format for one construct might not be appropriate when assessing the same construct using a different item format. These complexities add to the difficulty of conducting these studies.

Given that the foundation of all standardized forms of psychological and educational assessment is the consistency in test form and administration, accommodations research is growing. The psychometric questions are simple: Do accommodated versions of tests maintain their psychometric properties? At what point do departures from standardization begin to yield invalid or unreliable test scores? Do items function differently for groups with and without accommodations, and can meaningful inferences be made with confidence when the results of tests given with accommodations are used for placement, diagnostic, and policy purposes? While the questions appear simple, legitimate studies are difficult to implement primarily due to small sample sizes when subjects are sorted according to categories of disabilities (e.g. deaf, blind, learning disabled, etc.). The small sample problem is further complicated when sophisticated measurement techniques such as item response theory are used. Subsequently, to aggregate subjects across disability types is problematic due to the significant variations within a single disability and the potential for one person to have several different types of disability. In theory, there are potentially an infinite variety of accommodations if applied to the unique individual learning and cognitive characteristics among and between types of disabilities. From a measurement perspective, this is a mind-boggling premise but illuminates the complexity inherent in developing comparable tests when standardized procedures are altered for the disabled.

Demonstrating test comparability by using classical equating techniques is also plagued with methodological challenges. The 'classical' methods for equating call for random selection of two groups and then assigning each group to either a linear or percentile technique. Using a technique that utilizes a common set of 'anchor items' so that scores can be adjusted for ability between two groups relies on the groups being random and comparable. It is impossible to meet the requirement for randomly selected groups and it appears there is no standard technical solution available for precisely equating accommodated versions of standardized tests (Tenopyr, Angoff, Butcher, Geisinger & Reilly, 1993).

New approaches for equating are emerging and show promise but need further development since the classical procedures are not likely to be useful. For small samples (perhaps as low as 25), Livingston (1993) promotes the use of a chained equipercentile technique with log linear smoothing to produce bias free items even when the samples differ in ability. In this case, equating

occurs when the relationship between a set of anchor items and the remainder of the test is the same for the accommodated and non-accommodated groups. Mislevy, Sheenan and Wingersky (1993) take a different approach in that they argue for using expert judges to analyse item characteristics and factors that effect difficulty. This approach would ostensibly remove the theoretical, political, or practical factors that make it difficult to apply traditional equating standards. This approach would also require little or no data to make comparisons about comparability. Other psychometric issues that need to be considered when tests are presented with accommodations are reliability, content, construct, and criterion validity, fairness, differential item functioning (DIF), and robustness, to name the most important technical properties of a test. See Geisinger (1993) for a detailed discussion of these issues.

COMPARABILITY STUDIES

Willingham and his colleagues at the Educational Testing Service (ETS) (Willingham, Ragosta, Bennett, Braun, Rock & Powers, 1988) completed one of the first and most comprehensive reviews of test accommodations for people with disabilities taking the *Scholastic Achievement Test* (SAT) and the *Graduate Record Examination* (GRE). In terms of criterion-related validity, accommodated versions of the tests produced different outcomes for different disabilities than standard administrations. Overall comparability was found between standard and non-standard administrations of the tests with respect to internal reliability, factor structure and differential item functioning (DIF). However, test accommodations underpredicted first year college performance for students with hearing impairments, overpredicted first year performance for students with learning disabilities and physical disabilities, but produced comparable predictions for students with visual impairments.

More recent studies conducted with data generated from large-scale school accountability assessments have produced additional information. In the state of Maryland, Tippets and Michaels (1997) found the factor structures of several portions of the state test given with accommodations to be similar to the standard administration of the test. In Kentucky, Koretz and Hamilton (1999) detail the comparison of the large-scale tests given to students with disabilities using a variety of accommodations to standard administrations. In addition to the overall underperformance of the students with disabilities, differences were more noticeable among elementary students on multiple-choice items and more noticeable among students in higher grades on open-response items. Also, it was reported that DIF was apparent for students who used accommodations for both item formats and that the correlations among parts of the assessment when accommodations were used may indicate that the dimensionality of the assessment was changed.

It can be argued that comparing group data between individuals who receive test accommodations with those who do not misses the essence of why accommodations are given in the first place. That is, they should be tailored to the individual needs of the test taker and therefore analyses should be at the individual level. From this perspective Fuchs, Fuchs, Eaton, Hamlett and Karns (2000) provided students with and without learning disabilities with a variety of accommodations during maths calculation and problem-solving items. On traditional maths items students with learning disabilities did not benefit differentially but did receive a greater boost on problem-solving items that apparently presented greater reading/writing demands. Their results indicate that accommodations are often misjudged or overused by teachers and can have the effect of inflating a student's score.

FUTURE PERSPECTIVES AND CONCLUSIONS

Questions about the comparability of scores between accommodated and non-accommodated test administrations ultimately focus on the inferences made about the test results and the faith consumers have when using the results to make decisions. Professional judgement plays a pivotal role when accommodations are selected, implemented, and when test results are aggregated with scores from standard test administrations. Messick (1995) has pointed out that validity is an empirical evaluation of the meaning and consequences of measurement and that the

appropriateness, meaningfulness, and usefulness of score-based inferences are inseparable. From his framework, accommodations strive to remove construct-irrelevant variance without inducing or interfering with construct under-representation. Empirical checks between accommodated and non-accommodated versions of tests can only explain the relationships to a point. While it has been demonstrated that testing and school professionals believe few if any accommodations violate construct validity to a significant degree, more research is needed if results from accommodated versions of tests are considered equal to others.

TEST ADAPTATION/ TRANSLATION METHODS

INTRODUCTION

During the decades the interest in cross-cultural studies has increased. These studies involve groups without a common language. The traditional approach of making close ('literal') translations of (usually Western) source instruments for all target languages, though still widely used, has been challenged. It is appreciated that an exclusive focus on the linguistic aspects of a translation does not address the question, to what extent the item contents are adequate in all target languages. Similarly, it is increasingly appreciated that in order to translate psychological instruments linguistic competence is necessary though insufficient (Geisinger, 1994; Hambleton, Merenda & Spielberger, 2001). Also needed are knowledge of the target cultures

and expertise in designing psychological instruments. Modern translation projects pay much attention to the question of how cultural, psychometric, and linguistic knowledge can be combined so as to optimize their adequacy in each of these domains (e.g. Schroots, Fernández-Ballesteros & Rudinger, 1999).

ADOPT OR ADAPT?

Linguistic, psychometric, and cultural criteria may lead to different translations. Linguistic criteria involve equality of, among other things, semantic meaning, comprehensibility, readability, and style. Psychometric criteria involve the need to follow good practice of item writing and to assess the adequacy of test translations using statistical means (analysis of bias and equivalence: (see entry on 'Item Bias'). Cultural criteria involve the appropriateness of item contents and compliance with local norms and habits. Depending on the degree of convergence of the three criteria, two different options in test translation may be appropriate (Van de Vijver, Fons & Leung, 1997; Van de Vijver & Poortinga, 2001).

The first option is called *adoption*. It amounts to a close translation of an instrument in a target language. This option is the most frequently chosen in empirical research because it is simple to implement, cheap, has a high face validity, and retains the opportunity to compare scores obtained with the instrument across all translations. The aim of these translations often is the comparison of averages obtained in different cultures (Does culture A score higher on construct X than does culture B?). Close translations have an important limitation: they can only be used when the items in the source and target language versions have an adequate coverage of the construct measured on items showing bias. Standard statistical techniques for assessing equivalence (e.g. factor analysis, see Behling & Law, 2000, and Van de Vijver, Fons & Leung, 1997) should be applied to assess the similarity of constructs measured by the various language versions. However, even when the structures are identical, there is no guarantee that the translations are all culturally viable and that a locally developed instrument would cover the same aspects.

The second (and more modern) option is labelled *adaptation*. It usually amounts to the close translation of some stimuli that are assumed to be adequate in the target culture, and to a change of other stimuli when a close translation would lead to linguistically, culturally, or psychometrically inappropriate measurement (e.g. a coping questionnaire has the item 'watches more television than usual' to express the idea of seeking distraction. In areas without electricity or a low density of televisions this item should be adapted. A behaviour could then be identified that comes close to the original in terms of psychological meaning.). The validity of the new measure can be examined by scrutinizing the nomological network of the instrument (e.g. by correlating scores obtained with the instrument with scores on locally developed measures). Comparisons of scores obtained with adapted instruments, using a *t* test or analysis of variance, are impossible. However, recent advances in psychometrics such as Item Response Theory (see entry on 'Item Response Theory') and Structural Equation Modelling (e.g. Byrne, Shavelson & Muthén, 1989) allow for numerical score comparisons across language versions even in the cases of test adaptations.

The choice for either adopting or adapting an instrument can be based on various factors. If the aim is to compare scores obtained with an instrument in different cultures, a close translation is the easiest procedure. However, the cultural adequacy of the instrument in the target culture has to be demonstrated. The 'quick and dirty' practice of preparing a close translation, administering it in a target culture, and comparing the scores in a *t* test without any concern for the cultural and psychometric adequacy of the measure is hard to defend. If the aim is to maximize the ecological validity of the instrument (i.e. to measure the construct in a target culture as an adequate way), the choice for an adaptation is more obvious.

In the last decades, various techniques to produce translations and examine their accuracy have been proposed. Table 1 provides an overview. A good example of a modern, integrated approach to test translation that features linguistic, cultural, and psychometric aspects can be found in the *Guidelines for Adapting Educational and Psychological Tests* (Hambleton, 1994; Van de Vijver & Hambleton, 1996). A description of the various stages of a prototypical translation project is given in Table 2.

Table 1. Common translation designs and their advantages and disadvantages

Procedure/design	Description	Advantage	Disadvantage
Procedures to produce translation			
Translation/back translation (Brislin, 1986)	Independent forward and backward translation; translation is considered to be accurate if original and back translated text are identical.	Can be applied even when researcher does not know target language and culture.	Can produce stilted language; does not identify areas of test where an adaptation would be needed.
Decentring (Werner & Campbell, 1970)	Words and concepts that are specific to a particular language or culture are eliminated and the remaining, presumably unbiased instrument is translated.	Powerful tool to identify bias, removes cultural idiosyncrasies.	If cultures are far apart, the core of common items may be small and may poorly reflect underlying construct.
Convergence approach	Each researcher designs an instrument for his/her culture; all instruments are translated and administered everywhere.	Can provide valuable insight in bias.	Laborious.
Committee approach	Persons with different expertise or cultural background prepare translation.	Synergy by combining different types of cultural, linguistic, and/or psychometric expertise.	Laborious; psychological factors such as dominance of group members may be important.
Study designs for checking accuracy translation			
Working with bilinguals	Administration of original and translated instrument to bilinguals.	Control of group differences as groups taking both language versions are optimally matched.	Impractical when working in multilingual projects; bilinguals are not a random sample of population (potentially poor external validity).
Working with monolinguals	Administration of original and translated instrument to monolinguals in source and target cultures.	Can be easily implemented.	Samples may differ on outcome-relevant characteristics, such as age or education.
Random probes	Non-standard administration of translated version by asking participants to explain responses.	Check on similarity of item-as-intended and item-as-interpreted; useful in pilot stage of project.	Usually no comparative data available; informal check.
Parallel blind technique	Independent translations are prepared and compared.	Easy to implement.	Does not identify inappropriateness of item or test contents.
Judgemental procedures	Identify sources of cultural or linguistic bias (e.g.) by asking linguistic and/or cultural experts.	High face validity; optimal usage of cultural expertise; does not require data collection.	Need to establish inter-rater reliability; judgements may be inaccurate.
Post hoc procedures for determining translation accuracy			
Statistical procedures	Use of extensive set of tools to assess equivalence.	Strict test of accuracy; can and should be combined with other approaches.	Some procedures require huge samples; statistical procedures are often combined with specific designs (e.g. studies with bilinguals) and, hence, 'inherit' their problems.

Table 2. Steps in a test translation project (from Hambleton & Patsula, 1999)

1	Ensure that construct equivalence exists in the language and cultural groups of interest.
2	Decide whether to adapt an existing test or develop a new test.
3	Select well-qualified translators.
4	Translate and adapt the test.
5	Review the adapted version of the test and make necessary revisions.
6	Conduct a small tryout of the adapted version of the test.
7	Carry out a more ambitious field-test.
8	Choose a statistical design for connecting scores on the source and target language versions of the test.
9	If cross-cultural comparisons are of interest, ensure equivalence of the language versions of the test.
10	Perform validation research, as appropriate.
11	Document the process and prepare a manual for the users of the adapted tests.
12	Train users.
13	Monitor experiences with the adapted test, and make appropriate revisions.

FUTURE PERSPECTIVES

From a theoretical perspective, translation studies do not constitute an area where major theoretical advancements can be expected, possibly with the exception of the area of machine translations. The recent, remarkable progress may continue. It may affect the practice of close translations. However, this progress is unlikely to change the practice of test translations in the foreseeable future, especially in the area of test adaptations. Analogously, new theoretical frameworks and statistical tools may refine procedures to assess equivalence.

More changes can be expected at a practical level. Procedures to enhance and examine the validity of translations are available but not yet widely applied. With the advent of multilingual studies, it is likely that researchers will begin to agree on steps that need to be taken in multilingual studies and on how to report these steps.

CONCLUSIONS

The momentum in test translations has moved from theory to practice. Frameworks for preparing test translations and testing their adequacy have been developed, with contributions from various branches of science, such as linguistics, cross-cultural psychology, cultural anthropology, and psychometrics. The emphasis is now moving to the application of these frameworks. The future will tell whether the procedures developed in the laboratory are practical, adequate, and sufficient in the field.

TEST ANXIETY

INTRODUCTION

'Test anxiety' refers to the set of phenomenological, physiological, and behavioural responses that accompany concern about possible negative consequences or failure on an examination or similar evaluative situation (Zeidner, 1998). 'Test anxious' students are characterized by a particularly low response threshold for anxiety in evaluative situations, tending to view test situations as personally threatening. They tend to react with extensive worry, mental disorganization, tension, and physiological arousal when exposed to evaluative situations (Spielberger & Vagg, 1995). Test anxiety is often accompanied by maladaptive cognitions such as threat perceptions, feelings of reduced self-efficacy, anticipatory failure attributions, and coping through self-criticism (e.g. Matthews et al., 1999). A widely accepted definition proposed by Spielberger (e.g. 1980) construes test anxiety as a *situation-specific personality trait*. 'Test anxiety' may also refer to stressful evaluative stimuli and contexts, and fluctuating anxiety states experienced in a test situation. In general, *trait test anxiety* and *evaluative situations* may be seen as interacting to provoke *states* of anxiety (Sarason et al., 1995).

Test anxiety research has prospered, in part, due to the increasing personal salience of test situations for people in modern society, making tests and their long-term consequences significant educational, social, and clinical problems for many. Indeed, test anxiety figures prominently as one of the key villains in the ongoing drama surrounding psychoeducational testing, as a source of both scholastic underachievement and psychological distress. Many students have the ability to do well on exams, but perform poorly because of their debilitating levels of anxiety. Test anxiety may also jeopardize assessment validity in the cognitive domain and constitute a major source of 'test bias', in that anxious examinees may perform less well than their ability and skills would otherwise allow. Much of the test anxiety research over the past half century has been conducted to help shed light on the negative effects of test anxiety on examinee performance and these concerns have stimulated the development of a variety of assessment methods, to which we now turn.

SELF-REPORT INSTRUMENTS

Self-report assessments of test anxiety responses are most often elicited via questionnaires. Self-reports have become the most popular format for assessing test anxiety because they are considered to provide the most direct access to a person's subjective experiential states in evaluative situations, they possess good psychometric properties, they are relatively inexpensive to produce, and they are simple to administer and score. Self-report paper-and-pencil questionnaire measures of *trait* measures ask subjects to report symptoms they *typically*

or *generally* experience in test situations, whereas *state* anxiety scales ask individuals to report which of the relevant symptoms of anxiety they are *currently* experiencing in a particular test situation. Next, we briefly walk the reader through a number of salient issues in the development and validation of self-report measures.

What to Measure: Conceptualization and Dimensionality

An initial conceptualization of test anxiety is essential in order to guide the development of the item pool, and facilitate the initial construct validity research. As a hypothetical construct, test anxiety may be inferred by measuring cognitive (e.g. self-focused thoughts and worries), affective (e.g. subjective tension), or behavioural (e.g. escape behaviour) indices. Lack of precision in defining and observing inner constructs such as test anxiety can lead to serious problems in assessment. Although some early questionnaires were unidimensional, most contemporary researchers accept the distinction made by Liebert and Morris (1967) between *Worry* and *Emotionality* as major components of test anxiety. Worry refers to cognitive concerns about the level of performance, failure, and comparison with others, whereas Emotionality refers to feelings of tension and self-perceived physiological arousal. Debate continues on the dimensionality of test anxiety, and so contemporary questionnaires differ somewhat with respect to their number of scales.

Item Selection and Scale Construction

It is important to begin assessment with well-written items, and awareness of how item format may influence their measurement properties. Over the years, a wide array of item formats have been employed; currently, Likert scales are the most popular. Test anxiety self-report scales are also plagued by a number of conventional threats to validity, including response biases such as acquiescence and social desirability, defensiveness and repression of test anxiety, and deliberate faking. Thus, attention to possible biases and careful statistical analysis of test anxiety scales is essential. Most scales have been constructed using exploratory factor analytic techniques. Confirmatory factor analysis was used early in the 1980s in test anxiety research to test the adequacy of the indicator–factor relationship in the measurement model of test anxiety scales and has also recently been employed for purposes of item analysis and selection. The new latent trait theory methods of scaling have rarely been used in scale development, but they have considerable promise for scaling of test anxiety items in the years to come.

In general, test constructors have succeeded in developing measures with fairly high internal consistencies, typically in the high 0.80s to low 0.90s, and test–retest stabilities typical of personality traits. The factor structure of subscales is somewhat more uncertain, with conflicting results from different studies. Also, regrettably, few of the existing self-report instruments allow standardized comparisons to be made across independent investigations, although most provide separate norms for males and females.

Validity

Empirical evidence to show that a test purporting to measure test anxiety is indeed valid for the designated purpose. A main problem for empirical validation lies in finding an acceptable criterion. Scores on ability tests, grade point average, observer ratings, behaviour in structured evaluative situations, and the like are good candidates for criterion behaviours. Evidence on the concurrent predictive validity of test anxiety scales is reviewed by Zeidner (1998). Test anxiety scores predict academic criteria such as those just listed. Meta-analyses (e.g. Seipp, 1991) suggest a modest negative association between anxiety and academic performance of around -0.2. Validity coefficients are higher for worry than for emotionality, as expected: -0.29 and -0.15 respectively, in Seipp's meta-analysis of 126 studies (156 effect sizes).

Test anxiety scales also require 'construct validity', i.e. the nature of test anxiety is understood by relating test scores to other psychological constructs within the framework of some overarching theory. The predominant theories are cognitive-psychological, focusing on the detrimental effects of worry on attention and retrieval from memory (Spielberger & Vagg, 1995). Sarason (e.g. 1984) has proposed that test anxiety is characterized by self-preoccupation and worry, such that intrusive self-denigrating thoughts ('cognitive interference') attract attentional resources that might

otherwise be allocated to task-related processing. The person's appraisal of their own performance impairment feeds back into additional worry, generating, in the worst case, a vicious circle of progressively escalating worry and interference. There is a rich empirical literature showing that test anxiety is associated with maladaptive self-referent appraisals and ineffective coping strategies consistent with the Spielberger and Sarason theories (e.g. Matthews et al., 1999).

Key Measures

The *Test Anxiety Questionnaire* (TAQ), by George Mandler and Seymour Sarason (1952), is regarded as the first acceptable measure of the trait construct. This 37-item scale inquires about symptoms of anxiety experienced by examinees under major academic evaluative situations. Split-half reliability coefficients in the high 0.90s is evidenced for the TAQ, and test–retest correlations of 0.82 over a 6-week interval have been reported. Correlations of 0.59 between scores on the TAQ and behavioural ratings of overt manifestations of anxiety (perspiration, restlessness, inappropriate questions, and laughter) provide evidence of concurrent validity. A 'downscaled' version of the TAQ for children, the *Test Anxiety Scale for Children* (TASC), by Seymour Sarason and his co-workers (Sarason, Davidson, Lighthall & Waite, 1958), consists of 30 items dealing with anxiety in evaluative situations at school which subjects respond to with yes/no (e.g. 'Do you worry more about school than other children?'). Test–retest reliability coefficients in the low 0.70s are reported for the elementary school grades and internal consistency reliability coefficients for the TASC are reported to range from 0.82 to 0.90. TASC scores evidence concurrent validity when correlated with gross intellectual indicators, such as group IQ and achievement test scores. Factor analytic studies of the TASC have, with some exceptions, obtained the following four factors: 'Test Anxiety', 'Poor Self-Evaluation', 'Remote School Concern', and 'Somatic Signs of Anxiety'.

A second generation of test anxiety scales was spawned by Irwin Sarason, Seymour Sarason's younger brother. The *Test Anxiety Scale* (TAS; Sarason, 1978) is a trait measure of test anxiety, and represents a shift in focus from the situation to the person. The TAS consists of 37 items (originally consisting of 21 items taken from the TAQ), written in a true–false format and summed to obtain a total score. Test–retest coefficients in the 0.80s have been obtained for intervals of several weeks in the current 37-item version. Total TAS scores corrrelate highly with other test anxiety measures and also have been found to relate to task-debilitating and reported difficulty working under pressure. A factor analysis of the 37-item TAS yielded the following two-factor solution: (a) cognitive concern and worry about oneself and one's performance on tests, and (b) apparent consequences of this intense worry (including interference with effective cognitive functioning and a variety of physical and emotional consequences). Though it lacks sufficient normative data and sufficiently replicated information regarding the psychometric properties of this scale, the scale has been widely used in research on the nature and treatment of test anxiety. An additional scale developed by Sarason in 1984, the *Reactions to Tests* scale (RTT; Sarason, 1984), is a multidimensional measure of test anxiety, developed to gauge the following four theoretical dimensions of test anxiety: Worry (e.g. 'Before taking a test I worry about failure'), Tension (e.g. 'I feel distressed and uneasy before tests'), Test-Irrelevant Thinking (e.g. 'During tests, I wonder how the other people are doing'), and Bodily Symptoms (e.g. 'My heart beats faster when the test begins'). Each scale of the RTT is composed of 10 items, yielding four factorially derived subscale scores and a total score. Subjects are asked to mark the intensity of their responses on a scale from 1 ('not at all typical of me') to 4 ('very much typical of me'). Sarason (1984) reported subscale internal consistency reliabilities ranging from 0.68 to 0.81 for the total scale and 0.78 for all 40 items.

The *Worry and Emotionality Questionnaire* (WEQ) was developed by Liebert and Morris (1967) to measure what they believed to be the two major components of test anxiety – Worry (W) and Emotionality (E). Worry refers to cognitive concerns about such things as level of performance, failure, and comparison to others (e.g. 'I do not feel very confident about my performance on this test'). Emotionality refers to self-perceived physiological arousal and upset ('I feel my heart beating fast'). Scoring is along a 5-point Likert scale. In constructing the WEQ, five W and five E items were chosen from the TAQ on the basis of their general factor loadings content validity regarding

the dimensions involved. Alpha reliabilities for the W and E scales are in the 0.79–0.88 range. Scale validity has been demonstrated in the inverse relationship of performance-related indices to both Worry and Emotionality.

The most prevalent contemporary measure is the *Test Anxiety Inventory* (TAI; Spielberger, 1980). The TAI is a 20-item self-report scale based on two conceptualizations of test anxiety. The 20-item inventory consists of 8-item subscales for Worry ('Thoughts of doing poorly interfere with my concentration on tests') and Emotionality ('During tests I feel very tense'). The instrument has been translated into over a dozen languages including Arabic, Chinese, Dutch, German, Hindi, Hebrew, Hungarian, Italian, Japanese, Korean, Norwegian, Persian, Portuguese, and Spanish. The test manual (Spielberger, 1980) reports that alpha coefficients for the TAI total scores are 0.94 or higher, for both males and females. Although the internal consistency for the subscale scores is found to be somewhat lower than for the TAI total scale, the subscale alphas were all reported to be 0.86 or higher, with a median alpha of 0.90. Furthermore, the manual reports test–retest reliability to be in the range of 0.80–0.81 for 2-week to 1-month periods in a variety of student groups. The author provides impressive correlational evidence for the construct validity of the TAI. The TAI demonstrates strong convergent validity with the TAS ($r = 0.82$ for men and 0.83 for women), and is negatively correlated with both study skills ($r = -0.48$ for men, -0.14 for women) and grade point average ($r = -0.31$ for men, -0.18 for women). Furthermore, the TAI is modestly ($r = -0.22$), though consistently, related to academic achievement indices. Although a number of exploratory factor analyses have substantiated the two-factor structure of the TAI, confirmatory factor analyses tend to yield inconsistent results.

Benson and her co-workers (Benson, Moulin-Julian, Schwarzer, Seipp & El-Zahhar, 1992) combined the TAI and RTT scales to form the *Revised Test Anxiety* (RTA) scale, an 18-item multidimensional scale. The instrument produces four factorially derived subscale scores: Tension, Worry, Bodily Symptoms, and Test-Irrelevant Thinking. This scale takes advantage of the strong psychometric foundation of the TAI as well as the promising evidence for the multiple dimensions of the RTT. A unique feature of the RTA is its construction and validation through the use of extensive multi-national factor analysis and cross-validation procedures. Specifically, the scale was developed by subjecting the non-redundant items from the original RTT and the TAI to extensive multi-national factor analysis and cross-validation procedures based on a sample of 346 US, German, and Egyptian students. The RTA was then cross-validated using a second multi-national sample of 353 students. Cronbach's alpha for the 18-item RTA was 0.88. The Tension and Worry subscales showed reliabilities of 0.82 and 0.79 respectively, whereas the Bodily Symptoms and Test-Irrelevant Thinking subscales were lower, 0.68 and 0.67, respectively. The chi-square test of model fit for the 18-item four-factor RTA showed acceptable fit as did the cross-validation of the RTA.

ALTERNATIVE ASSESSMENT PROCEDURES

Think-Aloud Procedures

Think-aloud procedures are designed to assess the contents of consciousness in examinees while they are engaged in test taking, without imposing the researchers' preconceptions on respondents, as questionnaires may do. Subjects are asked to verbalize anything that comes into their minds, while working on the cognitive tasks given. The thoughts are then coded on relevant dimensions, such as their positive valence ('Problems are simple') or negative valence ('Not enough time left').

Physiological Measures

Test anxiety researchers have occasionally employed physiological measures of arousal (e.g. electrodermal activity) as indices of anxiety. Biochemical 'trace measures' assayed from blood, urine or saliva, such as corticosteroids and catecholamines, may also be useful, especially in studies involving prolonged exposure to evaluative stress (e.g. writing a doctoral dissertation). These responses should be immune to the problems of response bias endemic to self-report measures of anxiety. However, physiological indices suffer from a number of formidable methodological problems, including questionable construct validity, poor reliability, and low practicality in naturalistic field settings.

Behavioural Observations

Observations of behaviours such as excessive body movement and hand wringing may permit greater accuracy and more objectivity than self-report. Trained observers may utilize some standard set of observation categories in documenting test anxious behaviour. However, the use of observational procedures for measurement of test anxiety is rare and the psychological processes considered to be relevant to test anxiety are not very amenable to direct observation. Among the problems that adhere to these measures are: the complexity of coding schemes, observer bias and reliability, the reactive nature of the observation process itself, and the new latent trait theory methods of scaling high costs of conducting observational procedures. Table 1 presents a summary of the key measures of test anxiety.

FUTURE PERSPECTIVES: IMPROVING ASSESSMENT

We briefly present some suggestions for improving test anxiety scale assessment in light of current drawbacks, focusing on standardized scale development.

More Complete and Systematic Domain Coverage

Most scales focus mainly on cognitive and affective parameters of anxiety responses. The restricted content scope can be improved by employing more systematic domain mapping procedures (e.g. through facet theory) and better representation of additional facets in the test anxiety inventory. More attention to assessment of the processes supporting dynamic person–situation interaction across the various phases of a stressful evaluative encounter is also required.

Making Scales more Relevant for Clinical Purposes

Future scales need to target not just overall test anxiety, but also pathology associated with various antecedent or latent conditions, and a wider range of symptoms and consequences. The coverage of items needs to be expanded to reflect the phenomenology of high test anxious examinees, including such manifestations as panic attacks, total blackout, and anxiety blockage. Conversely, current instruments also tell us rather little about unusually low anxiety, ranging from lack of concern about evaluation and minimal motivation, to supreme self-confidence or high self-efficacy.

Differentiating between Adaptive and Maladaptive Manifestations of Anxiety

Current scales do not adequately separate maladaptive anxiety effects from those which may be adaptive, such as increased motivation. Future measures might distinguish between facilitating and debilitating arousal, and cognitive processes that are realistic (e.g. worrying about a genuinely threatening exam) and those that are unrealistic (e.g. those prompted by an exam covering familiar material).

CONCLUSIONS

Self-report test anxiety questionnaires have well-attested predictive and construct validity, but they may be open to a variety of response sets, including deliberate distortion and defensiveness. Future

Table 1. Classification of test anxiety measures: self-report versus alternative assessment procedures

Prevalent self-report scales	Alternative assessment procedures
Test Anxiety Questionnaire (TAQ) Test Anxiety Scale for Children (TASC) Test Anxiety Scale (TAS) Reactions to Tests (RTT) Worry and Emotionality Questionnaire (WEQ) Test Anxiety Inventory (TAI) Revised Test Anxiety Scale (RTA)	*Think-aloud procedures* (e.g. report anything that comes while working on the test) *Physiological indices* (e.g. electrodermal activity, muscle tension, GSR, trace measures, biochemical analysis of blood and urine samples) *Behavioural observations* (e.g. fidgety behaviour, nail biting, sweating, excessive body movement and tension, hand wringing, speed and accuracy of performance)

work might develop the assessment of physiological and behavioural test anxiety measures, and 'triangulate' assessment by means of converging operations. The assessment of test anxiety would also benefit from the application of the dynamic process models of contemporary stress theory. Rather than see test anxiety solely as a fixed property of the individual, it is important to explore how stable dispositions bias self-appraisal and coping in the context of the person's active attempts to manage the evaluative situation, and process cues towards performance adequacy.

Test anxiety scale scores must be understood within the context of a person's life and social milieu. Assessment requires appreciation of the various influences on anxiety score, including the person's academic history and learning skills, psychosocial adjustment, and behaviour during examinations. A simple composite test anxiety score should never be used in describing, predicting, or explaining an examinee's behaviour. Sound interpretation requires integration of various sources of data and assimilating them into an exposition that describes the examinee's functioning, detailing specific strengths and weaknesses, and predicting specific behavioural manifestations.

TEST DESIGNS: DEVELOPMENTS

INTRODUCTION

Test design refers to the process by which a test developer builds psychological tests – cognitive, affective, achievement, aptitude, certification, licensure, interest, motivation, personality, and others. The process addresses the issues of *why* a test is being used, *what* the test will cover, and

how it will test for those. A well-designed test does not happen by accident, but results from a systematic and informed series of choices on a number of issues. This entry reviews those issues, and emphasizes advances in the test development process. There are several more lengthy treatments of the topic, variously emphasizing item writing (Haladyna, 1999; Osterlind, 1998), analysis of test scores (e.g. Embretson, 1985; McDonald, 1999), cognitive psychology (Frederiksen, Mislevy & Bejar, 1993), or new developments (Hakel, 1998).

AN OVERVIEW OF THE TEST DESIGN PROCESS

Test design may be considered in stages. One first determines a *use* (*purpose*) for the test – that is, a reason for giving the test – and how test scores will be used. Tests are given to produce scores, from which some kind of decision about the test taker will be made. Less frequently, tests may secondarily be given to convey something about the ones giving the test. For example, a selection test for a company might serve as a job preview, or might convey a message, such as 'this is a high-tech operation', or 'we demand high levels of integrity'. The purpose may affect both the development of test specifications and the selection of item types and delivery means. A selection test to be administered worldwide might be delivered on the web; a self-assessment might be delivered in a magazine.

Next one develops specifications for the test, and decides how the test will be delivered. Following this are the *item writing*, *test assembly*, *review*, and *standard-setting* (cut-score) phases, with empirical item trials throughout, or whenever possible. Each of these stages are reviewed.

TEST USE

Tests are used in many ways. Some of the most important are: selection, classification, certification, licensure, promotion, diagnosis, student modelling, and self-assessment. *Selection* refers to using test scores to admit applicants into jobs, the military, or educational or training programmes. *Classification* refers to using scores to place applicants into jobs or programmes for which they may best be suited in light of the pool of selected individuals. For example, an employer might assign an applicant with strong social skills (e.g. based on a personality test) to a job involving working with people. Or a college may place an applicant into a remedial reading programme based on a reading score. Classification is similar to selection, but differs in several ways – e.g. in how the efficacy of the process can be evaluated (Scholarios, Zeidner & Johnson, 1997), and in the legal issues surrounding use. *Certification*, or *licensure*, refers to using test scores to formally ascertain one's level of proficiency in a technical or professional speciality. Examples are driver's licence examinations, architectural, auto mechanics, and real-estate licensure examinations, and nursing, business, teaching, law, and medical board examinations. *Promotion* testing is similar to certification and licensure testing, except that it pertains to movement through the ranks of a particular job, and does not typically imply any legal status associated with proficiency level, as a licensure test does.

Diagnosis refers to using test scores to identify applicant strengths or weaknesses. For example, a diagnostic achievement test might suggest that the individual needs remedial work in algebra, or has difficulties comprehending long passages. Diagnostic tests are often accompanied with remediation suggestions. *Student modelling* refers to using test scores to tailor instruction to students' knowledge. The 'model' refers to a representation of the student's current level of knowledge and skill in the domain being taught (e.g. algebra), typically at a molecular level (e.g. 'proficient in two-place addition', 'cannot perform carry operations in subtraction', etc.). *Self-assessment* may be seen as a factor crossing all these, but typically it refers to using a test score for self-awareness, such as knowing one's strengths, weaknesses, interests, and personality.

TEST SPECIFICATIONS

According to the AERA/APA/NCME standards (1999) test specifications refer to many different aspects of the test and how it is to be used and administered. These include its content, number of items, item formats, desired psychometric properties, arrangement of items and test sections, amount of time for testing, directions, administration procedures, and scoring procedures. In many applications, and increasingly in the future, additional properties such as the

psychological processes involved in test taking may be treated as part of the specifications.

Delivery

There are three primary delivery systems for tests: paper-and-pencil, computer, and world-wide-web. Most tests are paper-and-pencil. This includes the SAT, given every year to over 2 million students applying to college, mostly in the United States. The advantage of paper-and-pencil test administration is that test takers are familiar with the format, administration and scoring procedures have been well worked out, it is the least expensive format, and security procedures are known and reliable. Computer tests are rapidly gaining in popularity. There are a number of high-volume computerized tests, such as the Armed Service Vocational Aptitude Battery (ASVAB), given to about 1.2 million people per year applying for entry into the US Military Services, the Graduate Record Examination (GRE, 1.5 million, graduate school admissions), and the Test of English as a Foreign Language (TOEFL, 1.5 million, for admission to English-speaking institutions of higher education, given to those who speak English as a second language). The main advantages of the computer to deliver tests is that it enables adaptive testing, reducing testing time, and it permits item types that cannot be given in paper-and-pencil, such as ones requiring precise control or measurement of stimulus presentation and responses (e.g. reaction time tests, complex simulation tests). Another advantage is that response information is automatically recorded for easier analysis. Tests delivered on the web also enjoy these advantages, and additionally make 'anytime, anywhere' administration easy. However, ease of administration comes at a cost of decreased security, making web-administered tests more problematic in high-stakes uses. Additionally, web programming is newer than personal computer programming, and less software is available for web test development. Over time, security issues may be lessened, and web-programming tools will become easier to use. Consequently, web-delivered tests are likely to grow rapidly in popularity.

Item Types

A number of item-type taxonomies have been suggested (e.g. Haladyna, 1999; Kyllonen, 2000). Haladyna's proposes two dimensions – high versus low inference formats, and constructed-response versus multiple-choice – and discusses features, advantages, and disadvantages of the various item types. Constructed-response formats include essays, experiments, fill-in-the-blanks, short-answers, portfolios, and performances. Multiple-choice formats include conventional, matching, and true–false item types. High-inference formats are typically abstract, complex to construct, relying on judgement and subjectivity for their scoring, have low reliability, and invite bias. Low-inference formats are the opposite. Clearly, low inference, multiple-choice item types are most popular, but developments in the field seem to be largely focused on how high-inference constructed-response items might be made more reliable, inexpensive, and objective. For example, automated essay scoring is an area of avid research interest, with operational systems already in use, and rapid improvements in the works (Burstein & Chodorow, in press).

In the swiftly growing area of web testing, a taxonomy has been published in the form of a specification presented by the IMS Global Learning Consortium, Inc., a group developing and promoting open specifications related to online learning. Their 'IMS Question & Test Specification', which 'addresses the need to be able to share test items and other assessment tools across different systems' (from FAQ number 6), specifies various item types. They are organized into four categories: (a) logical identifier, (b) X-Y coordinate, (c) string, and (d) numeric. Logical identifier items are true–false, multiple-choice, multiple response (i.e. multiple choice with more than one correct answer), order (e.g. rank the following), and connect-the-points (e.g. draw a triangle). These item types may use text, images, and audio presentation, and may require either pointing (with a mouse) or 'sliding' (with the mouse). X-Y-coordinate items are image-hot-spot (point to a part of a picture, such as identifying the location of a city on a map), drag-and-drop (e.g. open a menu), and connect-the-points. String examples are fill-in-the-blank and short-answer, and numeric examples are fill-in-the-blank (with integers or reals) and numerical-entry-with-a-slider. The IMS specification may turn out to be a particularly important taxonomy as developers write software to this standard, to accommodate the various item types suggested.

Content (or Construct) Frameworks

A content (or construct) framework is a specification of the content of the test. For example, a test that measures problem solving might divide items by stage – understanding the problem, weighing alternative solutions, implementing those solutions, or evaluating the results. A reading comprehension examination might divide passages by science, social science, literature, or art. A science assessment might separate items by biology, chemistry, or physics. The basis for content distinctions can vary. The problem-solving distinction above is based on the 'stages of problem solving' literature. Content distinctions are often based on how curriculum is organized. An empirical basis is often useful – one derived from the results of a factor analysis, for example.

The main reason for including some kind of content framework in test specifications is to ensure that the domain structure is reflected in the test makeup. It would be inappropriate for a reading comprehension test, used for general college admissions, to include only history passages, for example. It is not only fair to have the test content reflect domain content, but is also likely to lead to higher test validity. How content sampling is conducted is an important consideration. Ideally, there would be a methodology to link domain content to test content, reflecting frequency and importance. In practice, this is often done by expert judgement.

Psychometric Factors

The main psychometric factors considered in test specifications are item difficulty, discrimination, reliability, and validity. Typically, tests comprise items of varying difficulty levels – easy, medium, and difficult. In initial test development, difficulty levels are unknown, but are estimated by those who write the items. Even with skilful and experienced item writers, it is tricky to obtain more precise estimates than easy, medium, and difficult, until considerable data have been collected. Personality items do not have difficulty per se, but can be characterized by the analogous factor of 'endorsement' rate (e.g. the percentage of people who endorse the item, or say it is characteristic of them, for example). Endorsement is interchangeable with difficulty in how it can be treated in test specifications (e.g. a personality inventory could consist of items with low, medium, and high endorsement rates).

Discrimination refers to the degree to which item performance correlates with overall test performance – this is often called a 'part–whole' correlation. It is usually desirable to have items with medium to high correlations with the rest of the test items. Low correlations can indicate problems with the item (either low reliability, or the item is measuring a construct different from what the other test items are measuring).

Reliability is a property of a test score (as typically computed from several items) for a sample or population of test takers. It is a measure of how someone's test score would remain constant, relative to the scores of others, if the test (or another version of the test) were administered again. As such, it is a relative measure: it is actually a ratio of score variance due to persons over the total amount of score variance (variance due to persons plus variance due to items). Thus, reliability is also a direct measure of the existence of true individual differences in test scores.

Validity is an index of the degree to which an item or test score reflects what it is supposed to measure. This can be computed by correlating test scores with criterion outcomes, such as school grade point average (criterion validity), or with similar test or factor scores (construct validity). It can be determined during the construction of the test itself, for example, by developing items by sampling from texts, or by interviewing experts (content validity). An interesting new addition to the list of validity types is 'consequential' validity, which refers to the effects the test has on those who take it and those institutions that use it for making decisions.

Exposure is an important property of items from high-volume, high-stakes tests, such as ones given for college admissions. It has to do with how many times a particular item has been seen by test takers. The idea is that the more times an item has been seen, the more likely that item will be 'compromised', and therefore ought to be 'retired' (not used in the future). Exposure is an important concept for adaptive tests, which consist of items that are exposed differentially, and therefore retired at varying times.

ITEM WRITING

Most of the time, test items are written by individuals familiar with the content being measured. This is particularly true with existing tests, where items are written to replenish the item pool. The psychometric quality of items will reflect the expertise of the item writer, with respect to both content and the process of item writing. Item writing is often regarded as an art, but there recently have appeared several excellent texts covering item writing rules and heuristics (e.g. Haladyna, 1999; Osterlind, 1998). Large testing organizations such as Educational Testing Service and American College Testing employ hundreds of professional item writers, possessing advanced degrees in literature, science, mathematics, and other disciplines, who specialize in particular tests or item types.

In some cases, particularly new tests with no extant items to serve as a guide, the task of item writing falls on a committee of domain experts. A committee of architects might write items for an architecture licensure examination; auto mechanics might write items for a mechanic's proficiency examination. Typically, professionals and specialists will not have the item writing knowledge necessary, and so such committees often include professional item writers who provide some training, or help the subject-matter experts with item writing.

TEST ASSEMBLY

Assembling items into a test is a necessary part of the test design process. During assembly, items are reviewed to ensure that the test meets specifications. In test design, typically many more items are written than can be used. That is because items are eliminated during assembly, or later, after data on item performance comes in, revealing some items' psychometric weaknesses.

Item review is a necessary part of test assembly. Reviewers evaluate items for several reasons. One is to determine whether items match test specifications. Another is to ensure clarity in what the test item is asking for, by eliminating ambiguous wording, excessive use of negatives, and other problematic language constructions. A third is to settle on the correct answer, which can be as simple as double-checking, and as complex as polling a group of experts and hoping for a consensus. A fourth kind of review concerns avoiding language that might be interpreted as unfair, biased, or insensitive to certain test takers or groups of test takers. In some cases, these reviews can be conducted by a single individual, but in high-stakes or high-volume tests it is often necessary to have different specialists conducting the various reviews.

After assembly, it may be necessary to set score standards. Standard setting is the process of deciding on a passing, cutoff, or qualifying score. There are several ways to do this; most involve a combination of judgement and test score data. Often a group of experts decides what constitutes a passing score. Implications of setting the passing score at a particular level can be explored by determining how many and which test takers achieve such a score. The passing score can be adjusted up or down based on that kind of information. A more involved procedure requires that experts estimate the number of 'qualified' individuals who would pass an item, considering items one at a time, then averaging those percentages to get a qualification score, a method known as the 'Angoff procedure'.

FUTURE PERSPECTIVES AND CONCLUSIONS

Research in test development is focused in several areas. One is in efforts to increase the efficiency of developing and scoring items – through item generation, and the use of natural language methods for presenting items – and interpreting responses, such as in essay scoring. A second is in efforts to consider a wider variety of item types to measure factors that have been traditionally confined to research studies, such as creativity and motivation. A third is in attempts to create items with a richer domain context, such as simulations. Advances in technology have aided attempts along these lines. Below are some additional new directions test design may be headed.

Personality and IRT Modelling

Item response theory (IRT) methods were developed originally with cognitive test items in mind – items with correct and incorrect answers.

Several researchers have proposed adapting IRT methods for personality and attitude items, which do not have correct answers, but which can be characterized by endorsement rates. The advantages and applications of an IRT approach apply to personality as well as ability items, for purposes such as item analysis (to identify and eliminate poor items), scale definition (to develop more reliable and valid scores), and adaptive testing (to reduce testing time) (Embretson & Reise, 2000; Smith, 2001).

Evidence-Centred Design

Evidence-centred design (Mislevy, Steinberg & Almond, 2001), or ECD, represents potentially a new approach to the development of tests, particularly those that are tied to a domain for specific purposes, such as licensing and proficiency examinations, or embedded tests that appear within a computerized instructional course. It also seems particularly important for 'high inference' applications when the test is a complex performance that must be interpreted as opposed to the more conventional 'low inference' measures. The basic concept of ECD is that test design ought to start with a consideration of the kinds of inferences the test administrator would like to make about the examinee. Given such inferences (e.g. 'this person is proficient in repairing automobiles', or 'this person is qualified to practise medicine'), the question is what evidence would lead to such inferences, and how confident would we be to make such inferences given the evidence. The final consideration is what tasks or situations could we present to the examinee to elicit relevant evidence. Although all test design concerns itself with these issues, ECD makes this inference chain more explicit, and relies naturally on Bayesian inferential statistics to link evidence and inferences.

Automatic Item Generation

Because item writing is a costly and time-consuming part of test development, there have been attempts recently to automate the process of generating items (Irvine & Kyllonen, 2001). Two general strategies seem most popular. In item cloning, one takes an existing item with desirable psychometric properties (e.g. good reliability and validity), and develops variants of it by changing item features, such as the names or numbers used in a mathematical word problem. In template generation, one generates items from an algorithm. This seems especially useful for items with a well-known structure, such as puzzle-like intelligence-test items. Both approaches appear promising, and developments are occurring rapidly. We are likely soon to see the application of natural language processing methods to automatic item generation, a major step forward.

CONCLUSIONS AND FUTURE PERSPECTIVES

A way to summarize many of the developments is that we are witnessing the transition from an art to a science of test design. This is an important advance and promises to lead to more economical, reliable, predictively valid, and construct valid tests. Among the developments that signal this change are the publication of standards (AERA/APA/NCME, 1999; IMS, 2001; ITC, 1999), the development of automated essay scoring systems, and the emergence of item generation models and theory as a framework for test construction. Among the most significant challenges in this transition is the capability for dealing with complex item types, often characterized by messy scoring requirements. Advances in the use of natural language processing methods, and Bayesian inferential statistics, as in the ECD approach, appear promising as ways to address some of these challenges.

TEST DIRECTIONS AND SCORING

INTRODUCTION

Test directions depend closely on the selected scoring rule. Therefore, this entry will mostly centre on the term *scoring*, which has two different meanings: (1) the process of attributing scores to the examinees according to certain rules, and (2) the selection of the scoring rule in the process of test construction. Both have been taken into account by the *Standards for Educational and Psychological Testing* (AERA, APA & NCME, 1999), although the first one has been given preference. The second meaning may have implications for the validity of the scores, and it is the one which has generated the most scientific research.

NORMATIVE ASPECTS

Concerning test directions, it is relevant to note that one of the rights of test takers is to be provided with as much information, where appropriate, about test scoring criteria as is consistent with valid responses. General advice about test-taking strategy should also be provided (AERA, APA & NCME, 1999: standard 8.2).

Following the semantic distinction on scoring, we will signal the standards related to scoring as a process (entry 5 on test administration, scoring and reporting) and as a decision on scoring rules (entry 3 on test development and revision).

Test Administration Scoring and Reporting

Standardized directions to examinees have the goal of ensuring that the procedure of test taking is properly understood. When tests are administered by computer or require special equipment, some practice time must be provided. Test takers will generally be informed of time constraints,

answering procedure, and, if pertinent, about when to omit item responses. Implicit is the goal of not providing unfair advantage to anyone.

With respect to the scoring process, standards 5.1, 5.2, 5.8 and 5.9 are summarized below: interpretability of test scores requires that tests be administered and scored following the developer's instructions, and only special situations or an examinee's disability would justify an exception. Scoring processes must be monitored in order to assure accuracy, correcting any systematic source of errors. When test scoring requires human judgement, adherence to scoring criteria should be checked regularly.

Test Development and Revision

Scoring rules are associated with *test framework* and *item format*, and must be consistent with the purpose of the test and facilitate meaningful score interpretation. Standards 3.6 and 3.14 are explicitly relevant to scoring.

Only after the nature of the item and response format has been specified, can scoring rules be selected. Scoring rules for multiple-choice items are obviously different from rules for short-answer items, extended-response formats, or performance assessments. In any case, all formats need some indication about how to score the responses. For short-answer formats, a list of acceptable answers is usually enough. For extended-response formats, instructions concerning the answers that will be scored correct have to be more detailed; in this modality, the scorers are usually provided with *scoring rubrics* specifying the evaluation criteria. For performance assessments, as well as for extended-response format, analytic or holistic scoring can be used – analytic scoring procedures give not only a total score on explicit criteria that reflect the test framework, but also separated scores for critical dimensions; holistic scoring procedures simply provide an overall score. The rationale of the various rules for multiple-choice testing programmes as well as the empirical data generated in the context of this format will be the object of the next section.

RESEARCH ON SCORING RULES

Multiple-choice items have many desirable characteristics (albeit some shortcomings, too); in addition, they are suitable for most of the purposes of testing, and therefore research studies on scoring rules have been mainly centred on this format. A major threat to the reliability and validity of scores on multiple-choice testing is guessing.

Guessing

The probability of guessing the correct answer is a ratio of one to the number of options ($1/k$). It is usual in educational contexts to adjust the directions and scoring rules to correct the expected effects of guessing in the sum of right answers, the traditional scoring rule. This is done by means of formula-scoring rules in which test takers' expected score will be the same whether they omit the answer to an item or guess at it randomly.

Two formulae have been proposed: (1) imposing a penalty of $1/(k-1)$ for each error, and (2) giving a bonus of $1/k$ for each omission. Both are linearly related by $S_{\text{bonus}} = [N + (k-1)\,S_{\text{penalty}}]/k$, where S means score and N is the number of items of the test. Consequently, if the asumptions of the formula-scoring model were true (i.e. errors are the product of guessing, and all guessing is at random), the ranking of subjects under these two conditions should be the same.

The validity of the scores could be still put into question if random guessing varied systematically between examinees, such as were it associated to aptitudinal, experiential or personality factors. Traub and Hambleton (1972) designed a study to assess the empirical effect of these scoring rules. Results showed that differences in reliability were favourable to the bonus procedure. With respect to criterion validity, no statistical difference was found, but effect sizes favoured the bonus procedure for every criterion they studied. In addition, the correlations between scores and personality variables did not systematically vary as a function of the scoring rules, which is inconsistent with the claim that encouraging guessing is in the interest of fairness.

However, Budescu and Bar-Hillel (1993) have proposed that examinees be taught to always answer. They compared the scoring rules on three dimensions: *strategic*, on how to maximize scores; *psychological*, on how actual examinees respond to the directions; and *psychometric*, on

the reliability and validity of the scores. They argue that, although psychometricians favour formula-scores, examinees have difficulties in understanding the corresponding instructions; and given that, from a strategic point of view, answering at random is never too prejudicial, encouraging test takers to always answer would eliminate the unfair advantage that often goes to risk-taking examinees.

But it should not be forgotten that guessing is found abhorrent by some people, and that it is also unethical in many real-life contexts, such as court witnessing or medical diagnosing, where accuracy is always preferred over quantity. It is difficult to justify that to evaluate children's knowledge, first they must be taught to guess! Taking into account this *educational* dimension, and expecting to discourage all sorts of guessing behaviour, Prieto and Delgado (1999a) tested a fourth rule – applying a penalty for errors that equals the premium for right answers. Globally considered, their results were favourable to the bonus rule, given that the level of errors remained high even under the most punishing condition.

If errors are not only the product of random guessing, but also of examinees' *miscalibration*, then instructions on strategy do not suffice to eliminate all errors, and applying a penalty for error is not, as pretended, a punishment for guessing. It seems that considerations other than guessing behaviour must be introduced in order to assess the performance of examinees.

Miscalibration

People monitor their memory reporting by deciding which items to omit as a function of the incentives for accuracy (Koriat & Goldsmith, 1996). However, the effect of monitoring on accuracy is dependent on the *calibration* of test takers, whose confidence judgements are not always diagnostic of answer correctness. Miscalibration is not easily altered (Gigerenzer, Hoffrage & Kleinbolting, 1991), and therefore it should not be expected to change by means of test-answering directions. This is a strong argument against penalty-based formula-scores. And there is still another reason to reject them: the implicit suggestion that, when guessing at random, right and wrong answers will cancel each other out is reinforcing the mistaken *belief in the law of small numbers* (on perception of randomness, see Bar-Hillel & Wagenaar, 1993). Under these instructions, examinees guessing at random should not be induced to believe that their scores will be the same as it would be had they omitted – this could be true in the long run, but it is only one of the possible outcomes in the actual situation. On the contrary, under bonus instructions, examinees know in advance the amount they will be rewarded.

Ben-Simon, Budescu, and Nevo (1997) tested various scoring rules involving self-assessment of *partial knowledge*, such as *elimination*, in which examinees are instructed to eliminate all distractors identified as incorrect, or *probability testing*, in which the probability that each option is the correct answer is reported. Their results confirm the existence of miscalibration, taking the form of an *overconfidence bias* for all the rules compared. Even though some of the rules can be very useful in order to assess different degrees of partial knowledge, the possibility of finding systematic association between overconfidence and individual differences variables jeopardizes the validity of the resulting scores.

FUTURE PERSPECTIVES

There is some evidence concerning the differential effects of scoring rules on different population subgroups, such as those defined by gender (Ben-Shakhar & Sinai, 1991; Prieto & Delgado, 1999b). Other subgroups (e.g. defined by minority status) could also be affected. Even though the effects were small, unfair classifications or decisions could reach a large portion of examinees were tests used in large-scale examinations. Predictive bias needs to be investigated.

The cognitive implications of asking examinees to judge their own state of knowledge during test completion must be researched, given that it could have a disruptive effect on examinee performance as well as having serious implications for construct validity.

CONCLUSIONS

The number right scoring rule seems to be inappropriate from both the psychometric and educational perspectives, and penalty-based scoring rules are also clearly inappropriate

from a psychological point of view, which also affects, although to a minor degree, the bonus-based rule, and partial-knowledge testing. However, it should be considered that passing a standard or getting high scores may be the main objective of examinees from a strategic point of view, but it is not the one that educators should foster. Teaching students to omit an answer when they are uncertain by means of rewarding seems far more adequate than teaching them to guess.

TEST USER COMPETENCE/ RESPONSIBLE TEST USE

INTRODUCTION

The purpose of this entry is to highlight some efforts to promote responsible use of tests throughout the world. Psychological and educational tests serve as key professional tools for psychologists and non-psychologists, and test publishers serve as gatekeepers to determine who has access to different types of tests. A persistent problem, acknowledged by professional associations and publishers, has been the misuse of test data and its subsequent potential harm to test takers.

THREE-LEVEL PUBLISHER CLASSIFICATION SYSTEM

The American Psychological Association (APA), five decades ago, addressed ethical use regarding the sale and distribution of tests (APA Committee on Ethical Standards for Psychology, 1950). Their

1954 technical recommendations (APA AERA & NCMUE, 1954) introduced a 3-level system for classifying tests, which emphasized the importance of professional credentials to justify access to tests at the highest level: level C (Moreland, Eyde, Robertson, Primoff & Most, 1995). Though the 3-level classification reappeared in the 1996 test standards, it no longer exists in APA standards or ethics codes (APA, 1992; American Educational Research Association et al., 1999; DeMers & Turner, 2000).

The current status of the 3-level classification and qualification requirements was examined using material from 8 USA test publisher catalogues. Seven of the publishers used a 3-level system, each with their own definitions and interpretation of the requirements, based on questions in their qualification forms. User questionnaires included level of training, professional association membership, licensure, course work, and workshops. Robertson, who in 1986 reported on a survey of test qualification forms of 13 major publishers, concluded that 'conditions of sale often were stated so generally that it was not possible to ascertain the exact criteria used to establish professional credibility' (p. 9). His conclusion still holds. Credentials and degrees serve as a crude screen to place test purchasers into broad categories that cover a wide range of criteria. The publishers require test purchasers to adhere to the APA test standards or to the standards of other professional associations.

EMPIRICAL TEST USER RESEARCH AND TRAINING

The Joint Committee of Testing Practices (JCTP), which now includes APA and six other professional associations, was established in 1985 to provide 'a means by which professional organizations and test publishers can work together to improve the use of tests in assessment and appraisal'. Two of JCTP's products dealt with empirical research on test user qualifications and training. JCTP formed the Test User Qualifications Working Group (TUQWoG) with the purpose of developing behavioural competencies for test users, based on two job analysis methods: the critical incident method and Primoff's job element method (Moreland, Eyde, Robertson, Primoff & Most, 1995).

The empirically based results included 12 minimum competencies for proper test use, such as 'avoiding errors in scoring and recording ... keeping scoring keys and test materials secure ... and establishing rapport with examinees to obtain accurate scores (Moreland et al., 1995: 16). A set of 86 specific test user competencies were derived from critical incidents gathered from 62 experts on 48 tests. Seven factors of test misuse were identified that dealt with: (a) comprehensive assessment, (b) proper test use, (c) psychometric knowledge, (d) maintaining integrity of test results, (e) accuracy of scoring, (f) appropriate use of norms, and (g) interpretive feedback. Furthermore, a system for empirically clustering tests for possible 3-factor or 8-factor solutions, based on likelihood of test misuse, was developed. A sample qualification form was developed and adopted by three test publishers and was adapted by others. Two of the eight test publishers currently ask test purchasers to accept and comply with Principles of Effective Test Use and another publisher lists Elements of Sound Testing.

At the suggestion of Anne Anastasi, who recognized that the prevention of test misuse needed to include test user education, a new JCTP group called the Test User Training Work Group (TUTWoG) was established. This group published *Responsible Test Use: Case Studies for Assessing Human Behavior* (Eyde et al., 1993). This book includes 78 case studies, based on critical incidents that were linked with the 86 specific competencies. Users are presented with focus questions for each case, and, on the back of the page for each case, are provided with an analysis of the case along with the relevant competencies and factors of misuse.

APA POLICY ON TEST USER QUALIFICATIONS

APA established the Task Force on Test User Qualifications (TFTUQ) to provide a policy on test user qualifications (DeMers & Turner, 2000). The task force was established in part because psychological test users may not have the knowledge and skill that is needed for optimal test use. The aspirational guidelines include generic qualifications for typical uses of tests and specific qualifications for the use of tests in

different settings or for specific purposes. The knowledge and skills guidelines include, for example, a detailed list of core psychometric and measurement knowledge topics. The section on qualifications for use in specific contexts includes employment, education, vocational/career counselling, healthcare, and forensic settings. Regardless of setting, the specific contexts deal with classification, description, prediction, intervention planning, and tracking. It is hoped that the guidelines will be used in training programmes to strengthen curricula coverage in measurement theory and psychometrics, and improve skill in administration, interpretation, and communication of test results.

INTERNATIONAL TEST COMMISSION

The International Test Commission (ITC) is 'an association of national psychological associations, test commissions, test publishers and other organizations committed to promoting effective testing ... and to the proper development, evaluation and uses of educational and psychological instruments' (Bartram, 2001). ITC has members in Western and Eastern European countries, North America, and some countries in the Middle and Far East, South America, and Africa. ITC's international effort to develop International Guidelines for Test Use was designed to pull together existing guidelines, codes of practice, and standards to create a coherent structure (Bartram, 2001). These materials were developed into a framework document, which formed the basis of the ITC Workshop on test use, held in Dublin in July 1997.

The competencies cover the following issues (Bartram, 2001a):

- professional and ethical standards in testing,
- rights of the test candidate and other parties involved in the testing process,
- choice and evaluation of alternative tests,
- test administration, scoring and interpretation,
- report writing and feedback.

The document (Bartram, 2001a) also includes appendices on:

- Guidelines for an outline policy on testing.
- Guidelines for developing contracts between parties involved in the testing process.
- Points to consider when making arrangements for testing people with disabilities or impairments.

The ITC guidelines were prepared to be generic guidelines for flexible use in different countries. They may be adapted to different cultural contexts, with different statutory requirements, and act as a resource for national professional psychological associations. Its purpose was to describe areas where there was consensus of 'good practice', without being prescriptive (Bartram, 2001b). The guidelines represent the work of psychological and educational testing specialists from numerous countries.

The document was designed to be user friendly by categorizing the statements under 16 main headings and using a user-friendly format, which provides for the completion of a common stem. The headings are (Bartram, 2001b):

1 Take responsibility for ethical test use
1.1 Act in a professional and ethical manner
1.2 Ensure they have the competence to use tests
1.3 Take responsibility for their use of tests
1.4 Ensure that test materials are kept securely
1.5 Ensure that test results are treated confidentially
2 Follow good practice in the use of tests
2.1 Evaluate the potential utility of testing in an assessment situation
2.2 Choose technically sound tests appropriate for the situation
2.3 Give due consideration to issues of fairness in testing
2.4 Make necessary preparations for the testing session
2.5 Administer the tests properly
2.6 Score and analyse test results accurately
2.7 Interpret results appropriately
2.8 Communicate the results clearly and accurately to relevant others
2.9 Review the appropriateness of the test and its use.

The guidelines were issued in Stockholm in July 2000, and published in *International Journal of Testing* (2001). As of August 2000, translations were being made into these

languages: Chinese, Croatian, Danish, Dutch, French, German, Norwegian, Slovenian, Spanish (two versions, one for Spain and one for Argentina), and Swedish.

BRITISH PSYCHOLOGICAL SOCIETY

During the last decade, the British Psychological Society (BPS) (Bartram, 2001b) has been actively dealing with the problems of low quality tests and poor testing practices. BPS publishes test reviews and maintains a voluntary Register of Test Users.

BPS has developed a certification process for occupational/employment test users. Both psychologists and non-psychologists use the process. The topics covered in the process are as follows (Bartram, 2001b): 'test administration, basic psychometric principles and the use of test of ability and aptitude, and the use of more complex instruments, particularly those used in personality assessment' (p. 178). A variety of work samples is used in the assessments and verifiers ensure that the assessment process meets the same standards. So far, over 15,000 certificates have been issued, which provides BPS with funding for extension of its test use work. The process for certifying will soon be extended to the users of educational tests. The BPS certification process contributes to higher standards of test use in the United Kingdom.

CONCLUSIONS

Professional associations, such as the American Psychological Association, the British Psychological Society, and the International Test Commission, have been actively involved in providing guidelines for improving test use, educating, and evaluating test user competence. Among these groups, the focus is on test user competency, rather than on licensure and doctoral degrees.

TESTING IN THE SECOND LANGUAGE IN MINORITIES

INTRODUCTION

Standardized tests have become an indispensable tool in the assessment process and the results they produce frequently form the basis of decisions regarding competence, promotion, selection, or detection of pathologies that may greatly affect the personal and/or employment situation of the subjects tested. Due to the widespread use of tests for making important decisions, the possible influence of testing in the second language in minorities has become a constant research topic in recent years. Many hypotheses have been formulated regarding the influence of language when individuals are tested in a language other than their dominant one. However, although this influence is widely assumed to be present the way in which it affects test results remains unclear (López, 2000).

The term 'minority' has generally been used in a linguistic sense to refer to those persons whose native language is different from that of the majority, regardless of their level of fluency in this second language (Figueroa, 1990; Geisinger & Carlson, 1992), although the cultural differences associated with this are increasingly being taken into consideration as well. The problem of testing in the second language in minorities is not only an issue which is attracting growing interest, but is one which is being reformulated and approached from new angles due to the rapid social change being brought about at present: a direct consequence of migration and the globalization of the economy is that researchers are being led toward a multicultural and multiethnic map.

HISTORICAL PERSPECTIVE

The current situation can be better understood by analysing how the use of psychological and educational tests with minorities has developed over the years (see the reviews on this issue by Figueroa, 1990; Olmedo, 1981). Up until the mid-twentieth century, research was focused on the standardization of various tests of intelligence for subjects (particularly children) from minorities, it generally being assumed that they showed a lower level than the majority group. Bilingualism was seen as a negative phenomenon, a delay in intellectual development and an obstacle to achieving competence in the dominant language. Many of these studies ignored not only the impact of a second language on psychometric test scores, but also the interaction between such scores and the socio-economic and educational level of subjects.

After 1950, there was a gradual change in attitude toward the effects of testing of minorities, and linguistic and cultural factors, as well as the social, political and economic reality of these groups, began to be considered. The surge in research interest on this issue occurred especially in the United States during the 1970s, and was linked to the strong human rights movement. Unfair/invalid testing of minorities was considered to be an obstacle to social justice and economic opportunity. As a consequence, new laws were introduced in an attempt to reduce the discrimination in the testing of minorities and new assessment materials, which were neither ethnically nor culturally discriminatory, were called for. Thus, for example, the 1985 version of *Standards for Educational and Psychological Testing* acknowledged this concern and included a chapter entitled 'Testing Linguistic Minorities' which suggested ways of approaching the issue.

This gradual change in attitude has continued to the present day and the influence of culture, language, social status, education and many other factors on testing is now commonly accepted. Research on the issue aims to analyse these factors and define precisely their influence, emphasis being placed on the advantages and disadvantages of bilingualism, its effect on test results and possible solutions or improvements to the problem of testing of minorities.

THE CURRENT SITUATION

Widespread social interest in the equal treatment of minorities has been the main stimulus behind

studies on the role of linguistic competence and the issue of inter-language contact with respect to test results. Bilingualism has ceased to be considered as having a detrimental effect on the development of intelligence and learning and is now seen as a sign of cultural richness. However, there are many different opinions and disputed points of detail about how bilingualism affects test results, whether of intelligence, or personality.

In the area of intelligence some authors (Cummins, 1984; Reynolds, 1991) argue that bilingualism increases intellectual flexibility and enables certain cognitive skills to be improved. However, this effect may be reversed in children with insufficient development in the first language (the well-known Cummins' threshold theory). In order to avoid problems and measurement errors, other authors have suggested using non-verbal tests, which are supposedly free of linguistic contamination, instead of tests that rely on the dominant language (Figueroa, 1990; Duran, 1989). A constant finding seems to be that bilingual subjects score higher on non-verbal tests than verbal ones, but this solution results in a reduced predictive power for variables of academic achievement.

With respect to personality tests, the impact of the second language on test scores has not traditionally received as much attention as in the field of intelligence, but there is currently great concern to address the issue and provide any solutions which are required (López, 2000). Most researchers (Malgady & Constantino, 1998; Price & Cuellar, 1981) argue that when bilingual patients are tested in their native language rather than their second one, more pathologies are seen. This is because the ethnic similarity between the patient and the clinician increases the latter's skill in identifying the cultural forms of expressing symptoms, and in understanding both the meanings associated with specific experiences and the linguistic variation in the patient's thought and expression. Along similar lines, Marcos (1994) identified four categories of patient behaviour that are susceptible to being distorted or misinterpreted by clinicians who are only competent in the dominant language: the patient's general attitude toward the tester and the interview setting; motor activity, speed and verbal fluency; affective and emotional tone; and sense of self. All this makes it difficult for the clinician to distinguish between what is induced by a lack of linguistic competence and the tension this produces, and what is genuinely due to a psychiatric symptom.

Whatever the case, with respect to both intelligence and personality, it must be remembered that bilingual individuals differ considerably in terms of their receptive and expressive command of language. Malgady, Rogler and Constantino (1987) and Olmedo (1981) suggest using the language that maximizes the likelihood of the subject understanding the requirements of the test situation and being able to respond to the best of his or her ability in one or both languages. In order to achieve this, further attention must be paid to the type and degree of bilingualism of each individual at the point of testing. López (2000) suggests three aspects which should be taken into account: (a) identifying a subject's dominant language requires a systematic evaluation, part of which must include the subject's own view of his or her linguistic ability; (b) psychological functioning may be related to the language that a bilingual person uses as well as to the ability level in each of the two languages; (c) the amount of vocabulary used may vary according to the social context which is being evaluated: for example, in the case of immigrant children, second language vocabulary will be more developed in the academic context while their first language will be more developed in the family context. Therefore, it is essential that the tester can detect in which language the subject should be tested in order to optimize the accuracy of the assessment.

FUTURE PERSPECTIVES

The great impact of testing of minorities is clear and the amount of research on this issue in recent decades is proof of its importance. However, further work is undoubtedly required on several important aspects in order to provide new information about the process of testing and the accuracy of the subsequent assessment.

The latest editions of *Standards of Educational and Psychological Testing* and *DSM-IV* both consider the assessment of minority groups, but as Malgady and Constantino (1998) point out, it would be helpful to develop a set of explicit guidelines about how language and culture should be taken into account when making multiaxial diagnoses.

Another line of action would be to carry out measurement equivalence studies between

cultures, using existing methodologies which remain underused at present. The aim would be to determine the generalizability and transcultural equivalence of these constructs before applying them to other cultures. Allen and Walsh (2000), Brislin (1993) and Okazaki and Sue (1995) distinguish the levels of linguistic, metric and conceptual equivalence; these would be used to check, respectively, if test items have the same meaning, if a common metric can be used to measure the same attribute, and whether the underlying psychological construct has the same meaning for the minority group as for the majority group for whom the instrument was, in theory, developed (on this issue, see the entry on cross-cultural assessment in this encyclopaedia). In summary, comparing cultural difference should now be regarded as comparing cultural non-equivalence.

All the above must also be related to test bias analysis from the point of view of construct validity. In order for a test's multicultural validity to be established, it must be shown to be invariant across cultural groups (Van de Vijver & Poortinga, 1991). It is here that techniques of test and/or item bias analysis can be used (see the entry on 'Item Bias' in this volume), especially confirmatory factor analysis with multi-sample studies (Gómez, 1996) which highlights whether certain idiosyncratic characteristics of the cultural group influence test scores, in addition to the trait measured. The construct might vary among groups and there may be specific constructs for a given culture, in which case the way in which assessment with that instrument is interpreted will vary according to the cultural group.

Finally, consequential validity (Messick, 1995), whereby use of the test is considered in the light of the probable consequences of testing, must be taken into account. This forms part of the concept of overall validity, an interpretation of test scores which takes into account the consequences of such an interpretation.

CONCLUSIONS

The problems associated with testing in the second language in minorities are attracting growing interest in our social and cultural reality, a reality in which immigration is an increasingly common worldwide phenomenon and where the use of testing and interviews is ever more common.

The central problem is how to identify, define and analyse all those variables which may affect test results in a second language, so as to avoid bias against a given culture or minority group. Research on this issue suggests that the following are all relevant: the ethnic background of testers, their gender, the style of testing, the degree of bilingualism of the subject and tester, the subject's level of identification with each of the languages and/or cultures which are in contact, whether or not an interpreter is used, whether the test is administered in the second language, the native language or in both, and, in this latter case, the order in which it is given. Undoubtedly, further and more systematic research is needed to clarify more precisely the degree of influence and possible control of each of these variables so that minority groups can be tested fairly.

In general, authors tend to agree that in terms of assessment aims, testing should be carried out in the subject's dominant language as this is the best way of reducing errors. López (2000), Malgady and Constantino (1998), and Malgady, Rogler and Constantino (1987) suggest a culturally-sensitive individual approach to testing which requires a preliminary assessment of subjects' linguistic competence and their degree of preference and identification with the majority or minority culture. This is related to the problem of acculturation, the process which takes place when two or more cultures are in contact; the degree of acculturation affects problems of testing of minorities as it includes not only language acquisition, but also the acquisition of the majority culture's values, customs and cognitive styles. All in all, the aim is to guarantee the highest levels of precision when testing, using the language that maximizes subjects' ability to show their knowledge, feelings and symptoms.

Finally, it is to be hoped that the guidelines described above will, over the next few years, be fully taken on board and thus provide a useful complement to current findings. What is especially needed is the development of measurement instruments that enable constructs which are conceptually equivalent across different cultures and linguistic groups to be inferred, thus guaranteeing measurement equivalence and the fairness of testing in minority groups.

TESTING THROUGH THE INTERNET

INTRODUCTION

Many have hailed the Internet as opening up a whole new set of opportunities for advancing the science of psychometrics and the technology of testing. Others have expressed concerns that the growth in the use of the Internet for testing will lead to poor tests being developed, good tests being used badly and a growth of bad practice that will adversely affect not only individual test takers but also act to discredit testing in general. This entry will explore both the areas of concern associated with the Internet and the opportunities it affords. More extensive treatment of these issues can be found in Bartram (1997, 2000).

UNDERSTANDING THE INTERNET

In order to appreciate its potential and its dangers, it is important to understand what the Internet is and how it works. The Internet is, literally, an interconnected set of computer networks (hence, inter-net). These various networks are able to communicate with each other through the use of a common shared protocol (TCP/IP).

The Internet has been with us since the 1950s. In its early days, the Internet, as a means of communication, was difficult to use. Use of the Net was confined largely to academics and the military, and its main use was for email and file transfer. The advance that led to the Internet becoming part of our everyday life was the development of the world wide web in 1992. A 'web' is a collection of pages connected by 'hyperlinks'. By simply 'clicking' with a mouse on a hyperlink on one page, the user can move from that page to another. Web pages are accessed using a 'browser'. This is a piece of software that resides on the users' computers, which lets them interact with the Internet and display web pages. With the addition of search facilities, the main features of the current World Wide Web were defined.

Webs (that is, interlinked collections of pages) are held on a 'server'. This will deliver pages to users when they call up the web's domain name (or URL). A web can reside on one server or consist of sub-webs divided across a number of physical servers. The Internet, as the transport medium, takes care of the process of finding pages and delivering them to the user.

In its simplest form, the pages delivered over the Internet to a web user will consist of content defined by HTML (Hypertext Mark-up Language). HTML contains simple formatting and layout instructions that tell the user's computer how to display the contents of the page. HTML pages can include graphics, sound, and video as well as text. However, the more information HTML pages contain, the longer it takes to deliver them.

In addition to HTML pages, it is possible to download applications (known as applets) that can run on the user's computer independently of the Internet. Tests written in this way will continue to run even if the Internet connection to the user is broken. This approach provides the test designer with far more control. However, for security reasons, some users may operate in environments that forbid the downloading and running of applets.

In considering testing on the Internet we need to consider both the technical strengths and weaknesses of the Internet itself (as a transport medium) and the limitations that the www technology imposes on the design of tests and control over their delivery.

SECURITY

Security concerns tend to be very high on the list of those worried about the use of the Internet for testing. The concerns over security need to be considered in relation to various sets of data.

1. The test itself (item content, scoring rules, norms, report-generation algorithms, report content, etc.).
2. The test taker's identify – both authenticating the person's identity and preserving their confidentiality.
3. Test results – ensuring that only those eligible to access the test scores are able to do so.

While all the above are areas of concern, it is important to put these into perspective by considering how the Internet, as a testing medium, compares with the current alternatives: paper-and-pencil and stand-alone computer-based testing.

Test Security

The key feature of the Internet is that, apart from the browser software itself, all the application software and all the data resides on the server not on the user's computer. Herein lie some of the main advantages of Internet-based testing:

1. All the important intellectual property associated with a test (scoring rules, norms, report-generation algorithms, etc.) remains on the server under the control of the distributor.
2. This level of control provides the distributor with detailed knowledge about the use of their products: who is using what, and when. This has enormous potential commercial benefits.
3. The test software and reference data set only exists in one location. This ensures that all

users have access to the most up-to-date version. It also greatly simplifies the process of making changes, fixing 'bugs', updating norm tables and so on.

Authentication of Users

There is a range of levels of authentication that can be used. The distributor can either make a test open access, or exercise full control over who can access the test content, when they can access it and from where. Control can be exercised by requiring a username and password, or access can be limited to specific machines on the Internet (by only allowing those with particular IP addresses to use the test). By combining IP address checking with user passwords, a very high level of control can be exercised. Such a level of control was never possible for paper-and-pencil testing or for stand-alone computer-based testing.

While this level of authentication would be more than sufficient for managing access to personal banking information, it is not sufficient for ensuring that people are not cheating in a high-stakes testing situation. For such a situation, a person could pass their identification to another person who would actually take the test, or they could have a group of helpers with them while they complete the test. Further advances in identification technology (fingerprint recognition and retinal eye-pattern recognition) would not really solve the problem of security in this sort of high-stakes testing situation.

For this reason, it is likely that high-stakes tests will continue to require the presence of a test administrator to confirm the identity of the test taker and ensure the test is completed under the correct conditions. While this is often noted as a disadvantage of Internet testing, it is really no different to other forms of testing technology.

Protection of Test Results

All the data generated by test takers resides on the central server. By applying best practice to the management of the server, the security of all aspects of the data can be far better assured than would be the case if the data were distributed amongst the various test users. Not only does the centralization of data storage make it easier to manage but it also makes all test data potentially available for research and development purposes. This in turn can raise concerns in some people that they may be losing control over their data. Clearly, if the data are to be used for research and development purposes then this should be agreed with the data providers in advance. The service providers should have clear policies on how individual data are to be kept, for how long and who is allowed access to them. These details must be made clear to the test taker and be agreed to by the test taker before the data are collected.

Those developing Internet-based testing systems also need to consider the applicability of various countries' data protection legislation on the privacy of the data they will hold on their server. At present, the situation is not clear with regard to psychological test data as to what rights the individual test taker has over access to their data. As a matter of good practice, they should be provided with meaningful feedback about their test performance. However, the issue of whether they also have a legal right to access information such as item responses, or scale raw scores, is still not clear and may differ from one country to another.

PERFORMANCE

It is in the area of performance that the major limitations of the Internet are to be found. Testing makes two main requirements of the delivery medium. First, it should provide the means of controlling the timing of delivery. Second, it should be robust and not fail mid-way through a test.

In an ideal environment, every time a page is requested, the page should appear within a fraction of a second of making the mouse click. In practice, it can take seconds or even minutes for the next page to arrive. To reduce the delay between one page and the next, you need to increase the rate of flow of information to the browser, reduce the amount of information in the page, or start sending information before the page is requested.

The last of these is only possible if the pages are in a pre-defined fixed sequence. For most applications this is not the case. Making the container smaller relies on minimizing the use of graphics and other media items that require a lot of space. The most effective solution is to increase the flow rate. This is limited, at present, by three potential bottlenecks.

1 First, the server may not be able to produce pages at a rate fast enough to keep up with the demand. Increasing the server capacity and increasing the bandwidth of the server's connection to the Internet can overcome this problem.
2 Second, the user may be accessing the server through a slow connection (e.g. a 56k telephone modem connection). For high stakes supervised testing, this sort of limitation can be easily overcome by using higher bandwidth connections at the user end. For open access tests, there is no way of controlling this directly, though it would be possible to write software that only lets someone take the test if they are capable of receiving pages at a certain minimum rate.
3 The third problem is the biggest one, and relates to bottlenecks that can occur in the process of getting the page from the server to the browser. The routing of traffic round the Internet is not directly under the control of the service provider.

The last of these problems is one of telecommunications infrastructure and is a significant problem in those areas of the world where the Internet is in relatively early stages of development.

The most rapid delivery is only of value if it can be relied upon. Hang-ups and lost Internet connections can potentially terminate a test session mid-stream. For some tests, it is not practical simply to resume from the point at which a break occurred.

The easiest way to overcome these performance issues is to download any time critical material as an applet. This, at least, will ensure that the test administration is not dependent on the Internet for its timing and integrity. However, from the user's point of view, this may create another problem, if the connection is a slow one; the applet may take a considerable time to download.

Consistency of Appearance

The Internet poses some of the same problems as stand-alone computer-based testing. For example, the test distributor has no direct control over the user's screen size or resolution. For stand-alone systems software controls can be used to mitigate and control some of the extremes of variation in screen settings. For browser-based testing, however, the level of control is rather less. Browsers are designed to leave the user in control of navigation around the Web and to be able to examine and modify the page display parameters in ways that we would wish to prevent in a normal test-taking situation.

Furthermore, there is no one 'standard' browser. Currently, two browsers dominate the market: Internet Explorer and Netscape Navigator. Unfortunately, these do not display information in exactly the same way. As a result, a test will look different and may behave differently depending upon the browser you are using.

Again, the solution to these problems, where they are likely to compromise the integrity of a test, is to create the test within an applet that can be downloaded and run on the user's computer.

GOOD PRACTICE

Much of the concern over Internet testing relates to issues of good practice. These concerns relate to three main areas:

1 Ensuring that there is adequate control over the management of the assessment process.
2 Ensuring that feedback and reporting is of high quality and contained within procedures that reflect good practice in assessment.
3 Controlling the quality of tests delivered over the Internet.
4 Ensuring equality of access.

Management of the Assessment Process

Testing is a process involving a number of participants, each with differing roles. The exact nature and number of participants will vary depending on the nature of the test and the reason for testing. Typically the roles include:

- The initiator or 'sponsor' of the testing process
- The person responsible for managing the process
- The test administrator
- The test taker

- The person who will provide feedback to the test taker
- Third parties who will be provided with information consequent upon the testing.

In addition to involving various people playing various roles, testing follows a sequence of events:

1 The tests are chosen
2 The arrangements are made for who is to be tested, when and where
3 The tests are administered
4 The scores are derived and reports generated
5 The reports are delivered to the designated recipients
6 Feedback is provided to the test taker and/or relevant others.

The Internet provides the ideal medium for managing both the participants and the process. Some current systems manage the process as a project that requires certain resources, in terms of people and materials, and has a time-line with a sequence of tasks and milestones. The work-flow is managed using project templates that users can configure by entering the names of the various participants, selecting the instruments to be used and setting milestone dates for key points in the sequence of events that make up the testing process. The process is automatically managed by assigning tasks to people and communicating with participants by automated emails and hyperlinks.

The level of control that can be exercised over each participant is potentially configurable by the user. In this way, for example, it is possible to ensure that only qualified test users will have access to reports that require an understanding of a particular instrument or that only qualified test administrators are allowed to log test candidates onto the system.

Feedback and Reporting

Just as it is necessary in some conditions to ensure that there is a human test administrator or supervisor present to ensure that high-stakes assessments are carried out properly, so there will also be conditions where it is important to ensure that feedback is provided to a test taker by a qualified person rather than over the Internet.

Most computer-generated test reports are designed for the test user rather than the test taker (Bartram, 1995). Considerable care and attention needs to be given to reports that are intended to provide the sole source of feedback for the test taker.

In practice, the situations where feedback needs to be provided on a face-to-face basis will tend to be the same ones where the assessment itself needs to be supervised. As such, providing for this is no more of a problem than it would be for traditional paper-and-pencil testing. With well-designed Internet testing process-management software, the logistics of arranging for test sessions and feedback appointments are much simpler than for traditional assessment.

Test Quality

The effect on a test's psychometric properties of delivering it over the Internet must be considered. Examples of bad practice abound. For example, some people have taken timed, supervised, paper-and-pencil tests and put them onto the Internet as un-timed and unsupervised. Clearly, one cannot regard the Internet version as the 'same' test as the original.

In general, when a test is presented, where there is some medium other than the one in which it was developed, it is necessary to check the equivalence of the new form (Bartram, 1994). In practice, this is most likely to be an issue for timed ability and aptitude tests. Most research suggests that the data obtained from un-timed self-report inventories are not affected by whether the test is administered on paper or on computer (see Bartram, 1994).

Equality of Access

There has been much concern expressed about the Internet creating a 'digital divide' between those with access to computer technology and those without (Keller, 1996). This is currently true on a geographical basis, with nearly all of the infrastructure and development of business taking place in North America, Europe and Asia-Pacific. This will change over the coming decade, but for some time we will not be able to use the Internet as the sole source of recruitment and selection in countries outside these three main areas.

Within the developed world, there has also been concern about inequalities of access relating to age, race and gender. Most surveys show that age and gender differences in usage are disappearing as use of the net becomes more widespread. Hoffman and Novak (1999) found that although income explained race differences in computer ownership and Web use, education did not (though education and income are related). Furthermore, they found no difference between white and African-American students when students had a home computer. The key concern within the US is that 'the Internet may provide for equal economic opportunity and democratic communication, but only for those with access' (Hoffman & Novak, 1999).

CONCLUSIONS

The Internet has rapidly grown from a medium that was used by relatively few people, to a situation where it is now used by a substantial proportion of the population in the 'developed' world, with new users increasingly reflecting demographic distributions of age, gender and ethnicity (Bartram, 2000). As such, the infrastructure is now sufficiently widespread and accepted to make it increasingly likely that the Internet rather than paper will become the medium of choice for testing over the next 5 to 10 years.

Before long, a high proportion of homes in North America, Europe and Asia-Pacific will have direct interactive access to the Web through the use of fibre-optic cable TV links. This is likely to dramatically increase levels of home-based traffic and will open up new possibilities for educational and occupational assessment in the home.

Technologies are converging to the point where it will be increasingly difficult to differentiate between PCs, TVs and telephones. As this happens, so interactive voice-response (IVR) technology will develop and merge with current Internet-based and video-phone technologies to provide a future seamless interactive communication medium. Digital domestic phones have similar features to digital mobile phones. In 1997, the President and CEO of Nokia estimated that there would be 300 million mobile phone users by the end of 1998, rising to one billion by 2005, and that 'a substantial portion of the phones sold that year will have multimedia capabilities'. UMTS (universal mobile telephony services) will carry an average 144,000 bits/sec compared to the current 9,600 bits/sec of current mobile phones. It will be capable of performing multimedia functions, including Internet access and email.

We are likely to see rapid improvements in both bandwidth and reliability, enabling a far greater range of assessments to be delivered and managed. Along with that will come wide public acceptance of the Internet as a 'natural' medium with which to interact. It will become as familiar as the telephone, radio and television. As this develops, so we will see increasing realization of the potential of computer-based testing: *item-banking* and *adaptive testing*, the use of increasingly sophisticated *item-generation* procedures and the developing of exciting new *simulations* and *scenario-based assessments*.

COMPUTER-BASED TESTING, ITEM RESPONSE THEORY: MODELS AND FEATURES

THEORETICAL PERSPECTIVE: BEHAVIOURAL

INTRODUCTION

'Behavioural assessment is a misunderstood term that has been defined in various ways' (Cone, 1998: 26). In the early days of the discipline, it was common for definitions to rely on contrasts of behavioural assessment with more psychodynamically oriented clinical assessment. Thus, whereas behavioural assessment views specific responses of the client as a sample of other, similar behaviour, traditional clinical assessment views them as signs of underlying dispositions or traits. Behavioural and traditional clinical assessment both seek the causes of behaviour. These are likely to be found in contemporary environmental influences for the former, however, and in the early developmental history of the individual for the latter. Behavioural assessors look outside the person in the environmental context for controlling variables. Traditional clinical assessors look inside the individual, trying to understand the complex interplay of dynamic factors (traits) as they control external behaviour.

There continues to be a great difficulty distinguishing behavioural from other types of assessment. It is the thesis of the present entry that a clear understanding of the discipline results from dividing the subject matter of assessment into two major categories: (a) behaviour itself (e.g. 'hits others'), and (b) inferences about behaviour (e.g. 'is aggressive', and, therefore, has the trait of aggression). All assessment relies on observations of behaviour for its basic datum. Different uses of those observations permit the identification of two dominant theoretical perspectives. When *behaviour* per se is the subject matter of interest, we can view the assessment enterprise as 'behaviour assessment'. If some characteristic of a person other than behaviour is our primary interest (e.g. traits or dispositions), we can view the enterprise as 'behaviour*al* assessment'. When traits are the focus of assessment, they are reached indirectly via inferences from behaviour. When behaviour itself is the focus, it is reached directly by observing it. Minimal inference is involved (Fernández-Ballesteros, 2002).

In what follows, assessment methods common to both behaviour and behavioural assessment are initially described, followed by separate discussions of the two approaches. Within each, the subject matter of prime interest is treated first. The quality of the information the approach provides is discussed next. Accuracy, reliability, and validity are the primary concepts, though their relevance to the two perspectives varies. Conclusions and future perspectives comprise the final sections of the entry.

METHODS OF ASSESSMENT

Five frequently used methods to assess behaviour include: (a) interviews, (b) self-reports, (c) informant reports, (d) self-observation, and (e) direct observation. As illustrated in Figure 1, these can be arrayed along a continuum representing the extent to which they involve observations of the behaviour of interest at the time and place of its natural occurrence. The directness continuum (Cone, 1977) incorporates three important characteristics of behaviour: (a) its topography or form, (b) its occurrence in terms of time, and (c) its location in physical space. Methods at the direct end of the continuum (e.g. self-observation, direct observation) involve

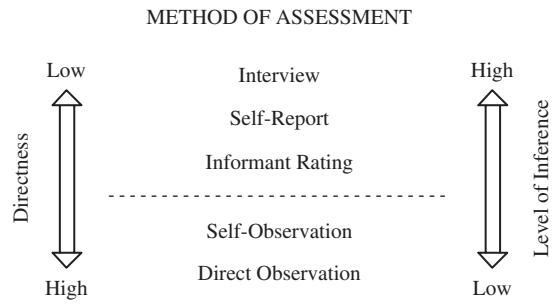

Figure 1. A three-dimensional scheme for organizing assessment methods in behavioural assessment.

observations of responses that are indistinguishable from the actual response of interest in terms of these topographic, temporal, and spatial features. Those at the indirect end (e.g. interviews, self-reports, and informant-reports) involve observations of responses that differ from the actual response of interest in one or more of these features. Indirect methods rely on representatives or surrogates of responses of primary interest. These surrogates are usually in the form of verbal reports by someone of their own behaviour (interviews, self-reports) or someone else's (informant report). Other things being equal, it is assumed that the highest quality data come from methods at the direct end of the continuum. That is, direct methods provide narrow-band, or focused, high quality information, whereas indirect methods provide correspondingly broader band, less focused, lower fidelity information.

BEHAVIOUR ASSESSMENT

Consider the terms 'behaviour assessment', 'quality assessment', 'health assessment', and 'maths assessment'. Distinguishing among these terms requires focusing on nouns representing the objects of assessment. That is, we assess behaviour, quality, health, and maths. Doing so does not imply *how* the assessment is to occur, however. As shown in Figure 1, there are a number of ways of assessing any one of these content types. In selecting an assessment method, it is important to be clear about the content or subject matter of interest. This is because some methods lend themselves more easily to assessing behaviour per se.

In behaviour assessment, the content of interest is behaviour itself. Behaviour can be viewed within a natural science perspective. From this point of view, it is seen as 'that portion of an organism's interaction with its environment characterized by a detectable displacement in space through time of some part of the organism and that results in some change in the environment' (Johnston & Pennypacker, 1993: 363). Seen in this way, the principles of measurement that apply to other natural phenomena are applicable to behaviour as well. For example, measurement in the natural sciences includes units that are absolute and standard. Behaviour occurs or it does not, and its frequency is determinable with reference to a true absence of behaviour or a zero point. These qualities mean units of measurement occur on ratio scales and yield scores that are fully manipulable using all four arithmetic operations (Frankfort-Nachmias & Nachmias, 1992).

Detectable displacements of some aspect of the organism can be observed and counted. These may be exceedingly small, as in the case of single neurons firing. Or, they may be relatively large, as in the case of swinging a golf club or throwing a ball. Assessment methods are selected to optimize observing behaviour, whether large or small. Moreover, direct observation of responses at the time and place of their occurrence is preferable to indirect observation that relies on surrogates from which behaviour is inferred. For example, observing actual movement of patrons between exhibits in a museum is preferable to inferring this movement from switch closures of electronic devices hidden under the floor (e.g. Bechtel, 1967). Observing the proportion of talk time occupied by husbands in conversations with their wives is preferable to relying on estimates of this proportion in the reports of the involved parties. Thus, an important characteristic of instruments used for behaviour assessment is their directness.

The size of the unit of behaviour assessed is also an important consideration. In the observation of hyperactive children, for example, we can record specific occurrences of 'out of seat', 'talks out of turn', and 'throws things', or we can consider these as interchangeable members of a larger class referred to as inappropriate behaviour. To be sure, even 'out of seat' is a collection of smaller responses and might be considered a behaviour class in its own right. Advantages of aggregating precisely determined responses into larger classes are increased reliability and validity of measures (Haynes & O'Brien, 2000). The logic of such aggregations must be carefully considered, however, in order to remain faithful to the original purposes of assessment. If our purpose is to learn something about behaviour per se, we are likely to prefer aggregates of responses that are functionally equivalent. If we are assessing to determine a person's position on a particular trait, our aggregate is likely to consist of interchangeable indicators equally determined by an underlying latent variable.

Behaviour assessment is at least 'the objective description of specific human responses that are considered to be controlled by contemporaneous environmental events and whose consistency and/or variability are directly related to the consistency and/or variability of their environment' (Cone, 1987: 2). Preceding the definition by 'at least' suggests it can be something more than the mere description of human responses. It can, for example, include a determination of just what those controlling environmental events are. Silva (1993) suggests this definition is at odds with the views of many others because it permits, but does not *require*, the performance of a functional analysis. Fernández-Ballesteros (2002) appears in agreement when she says functional analysis is an 'essence of behavioural assessment' (p. 1090).

It is well to separate the terms 'behaviour assessment' and 'functional analysis', and to appreciate that the latter requires the former, but not vice versa. Doing so recognizes behaviour assessment as the more comprehensive term, including in its reach any careful documentation of specific human responses, whether we search concurrently for their controlling variables or not. We cannot do a functional analysis without behaviour assessment, but we can do behaviour assessment without a functional analysis.

BEHAVIOURAL ASSESSMENT

Consider the terms 'behavioural assessment', 'psychological assessment', and 'educational assessment'. Distinguishing among them requires focusing on the adjectives representing an *approach* to assessment. That is, the terms tell us something about *how* assessment occurs. While they might also carry information as to *what* is assessed, there is no logical or syntactical requirement for them to do so. Whereas behaviour assessment communicates an interest in behaviour per se, behavioural assessment connotes an approach to assessment that may or may not have behaviour as its subject matter. Presumably, phenomena other than behaviour can be assessed with a behavioural approach.

Indeed, if we examine the types of phenomena appearing in the 'behavioural assessment' literature over the past 25 years, we find behaviour per se to represent only a small proportion. Often, the interest is in assessing a latent variable presumed to underlie behaviour and for which behaviour is of minimal interest in its own right. Rather, behaviour is taken as a sign of the underlying variable. When we view scores on an instrument as *determined* by an unseeable latent variable, it is that variable that is primary. Examples of such variables include 'assertion', 'anxiety', 'hyperactivity', 'autism', 'shyness', and 'heterosocial competence'.

Latent variable assessment (sometimes referred to as 'trait assessment') relies on behaviour as a sign or indicator of the underlying disposition. In doing so, it makes use of indirect measures such as interviews, self-reports, and informant reports. Responses to questions or items (indicators) comprising these measures are aggregated to provide overall scores that are used to infer how much of a particular trait a person has. Behavioural approaches to assessing anxiety from a triple response mode perspective are an example. Such latent variable forms of behavioural assessment often rely on indirect, high inference methods. Conversely, assessment focusing on behaviour per se tends to use direct, low inference measures.

Addressing both directness and inference continua simultaneously leads to the two-dimensional framework for classifying assessment methods represented in Figure 2. Direct observation assessment of family interaction via the FICS [Family Interaction Coding System] or having a client observe and record the number of cigarettes smoked (Quadrant A) are examples of direct observation methods that accept the behaviour at face value, making very low inferences about its meaning. Self-reported occurrence of depressive behaviour via the BDI [Beck Depression Inventory] or of social anxiety via the FNE [Fear of Negative Evaluation] (Quadrant D) are examples of indirect assessment methods that interpret scale item responses as indicative of the presence of an underlying disposition. Thus, behaviour is seen as a sign of the disposition and a person's score on the measure is used to infer the amount of the trait or characteristic possessed. Assessment approaches focusing on behaviour per se tend to fall in Quadrants A and C. Those using behaviour as a sign tend to fall in Quadrants B and D. Figure 2 helps clarify that the single most important characteristic distinguishing various approaches to behavioural

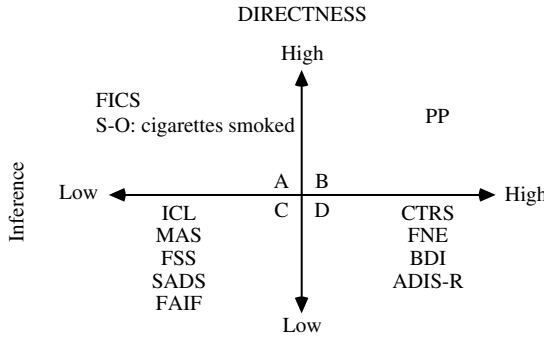

Figure 2. Classifying assessment devices in terms of directness and the level of inference associated with interpreting their data. assessment is the level of inference used in interpreting scores.

DETERMINING THE QUALITY OF BEHAVIOUR(AL) ASSESSMENT

The usefulness of scores from assessment procedures relates directly to the scientific adequacy of the procedure. Quality of assessment information is discussed under the headings of reliability and validity elsewhere in this volume, and will be mentioned only briefly here. The very important concepts of accuracy, and representational and elaborative validity are discussed as they are particularly relevant to behaviour(al) assessment and may not appear in other entries.

Accuracy

Defining one's subject matter as behaviour and viewing it as a natural phenomenon places it among a class of events for which the properties are determinable more or less definitively. Consequently, instruments used to assess behaviour can be evaluated in terms of how faithfully they represent or portray these properties. Those doing a perfect job are said to be accurate in the same way that a microscope representing the structure of a cell with a high degree of fidelity is said to be accurate. Important aspects of behaviour include its topography, frequency, latency, duration, and magnitude. These will be represented with fidelity by assessment instruments of the highest quality.

Accuracy is determined by comparing data from an assessment instrument against an incontrovertible index or state of nature about which relevant information is available. If the values returned by the instrument are consistent with the properties of the incontrovertible index as independently determined, we say it is accurate. For example, a scripted interchange can be written to portray a verbal interaction between a parent and child. The script includes positive comments by the parent at a rate of two per minute. If direct observations of actors portraying the script reveal such a rate, the observations are said to be accurate. The limits of that accuracy can be derived and used to qualify data resulting from using the instrument. Accuracy is not relevant in this sense for measures of latent traits which, by their very nature, are hypothetical and for which there are no incontrovertible indices.

Reliability

A reliable instrument is one that yields the 'same measurement values when brought into repeated contact with the same state of nature' (Johnston & Pennypacker, 1993: 138). Reliability and accuracy are related though not equivalent concepts. Independent observations such as those provided by two persons viewing the same behaviour might agree with one another and thus be reliable. Their agreement (reliability) implies nothing about their accuracy, however, as something other than the reportedly observed state of nature might be controlling their observations.

Validity

Accurate instruments may or may not be useful for other than descriptive purposes. That is, they will provide a faithful representation of behaviour, by definition, but this representation may or may not relate to anything. A parallel concept

applies in other forms of assessment when instruments are described as being reliable but not valid. In this context, it can be helpful to describe accurate instruments as showing representational validity but not elaborative validity (Cone, 1995; Foster & Cone, 1995). Campbell (1960) distinguished trait from nomological validity in a similar fashion, though he appears to equate the latter with construct validity.

REPRESENTATIONAL VALIDITY

Representational validity deals with the extent to which a measure faithfully portrays or reflects the thing being assessed. It is the limited form of validity said to exist when an instrument measures what it is supposed to measure. Accurate instruments represent behaviour with high fidelity by definition, thereby showing representational validity. Thus, when behaviour per se is the focus, accuracy and representational validity are synonymous. When latent variables are the focus, other qualities (e.g. structural characteristics of the instrument, content validity, internal consistency, sensitivity to change over time) are relevant to showing representational validity. The issue here is the extent to which the indicators (items) of a measure do a credible job of representing the underlying variable. Internal consistency analysis is relevant because higher inter-item correlations rule out multiple determinants, allowing the interpretation of scores to focus on fewer latent variables, preferably only one.

When a measure is thought to reflect an underlying disposition, relevant theory dictates the measure's content. If careful analysis of that content shows it to represent the variable with a high degree of theoretical fidelity, the measure is said to show representational validity evidence. Likewise, confidence in the measure's faithful representation of the underlying construct grows as it is shown to be unrelated to measures of other constructs from which it is supposed, theoretically, to be independent. Historically, this form of independence has been referred to as discriminant validity (Campbell & Fiske, 1959). We assume that a measure represents its underlying construct more precisely to the extent it shows minimal overlap with measures of unrelated constructs.

In the same vein, confidence in the representational validity of a measure increases when it correlates with other measures known to tap the same thing. That is, when data from alternative ways of assessing a theoretical construct converge, our confidence in the representational validity of each increases. Historically, the correlation of multiple methods of assessing the same thing has been referred to as convergent validity (Campbell & Fiske, 1959).

ELABORATIVE VALIDITY

If scores on an instrument enter into relationships with scores representing other phenomena, they can be said to be useful, thus showing a degree of elaborative validity. Their usefulness expands (is elaborated) as more and more such relationships are demonstrated.

When behaviour is the focus, an important form of validity evidence comes from functional analysis. Thus, covariation between antecedent and consequent environmental events and behaviour is examined to establish causal relationships. The presumption underlying this approach is that understanding is advanced by showing systematic variation in behaviour to coincide with variation in environmental events. For example, discussions of husbands' alcohol drinking might be consistently associated with greater visual attention from their wives than discussions of other topics (Hersen, Miller & Eisler, 1973). This relationship can lead to the hypothesis that alcohol-related discussions are maintained by wives' attention to their husbands. Accurate observations of the discussion topic are shown to have elaborative validity in this way. That is, they show a degree of usefulness in helping understand why the content of the conversations might contain references to the husbands' drinking.

The type of elaborative validity evidence of greatest relevance for latent trait measures comes from showing that their scores enter into nomological networks involving other latent variables with which they are presumed to relate. In other words, a measure of self-confidence gains in usefulness when its scores relate in anticipated ways to scores on theoretically relevant variables, e.g. heterosocial competence. This type of relationship is the essence of construct validity in trait-oriented assessment.

Other forms of elaborative validity evidence involve correlations between scores on assessment measures and practical criteria (so-called criterion-related validity). These apply to measures directed at behaviour or at latent variables. Messick (1995) expanded construct validity to encompass the entire test construction and validation process. In so doing, he effectively eliminated the usefulness of construct validity, because a concept that is at once everything is at the same time nothing (i.e. no thing).

FUTURE PERSPECTIVES

Future theorizing should address such issues as whether internal consistency is conceptualized better as a form of reliability (as currently viewed), or as a type of representational validity as implied above. In addition, practical ways of establishing accuracy should be developed. Finally, the development of higher order assessment systems in which observations at all levels of behavioural molecularity are carefully and systematically interrelated is needed.

CONCLUSIONS

Contemporary behavioural assessment is approached from multiple perspectives. The dominant ones involve focusing either on behaviour per se or on underlying latent variables. They do so using common assessment methods, but preferring direct and indirect methods, respectively. Inferences about the meaning of scores differ substantially across perspectives, with low and high levels of inference characteristic of behaviour and latent variable assessment, respectively. Ways of assessing data quality vary, depending on perspective. Accuracy, reliability, and validity (both representational and elaborative forms) are emphasized when behaviour per se is the focus, but accuracy is not applicable when assessing latent variables.

THEORETICAL PERSPECTIVE: COGNITIVE

INTRODUCTION

Generally, the terms 'cognition' and 'cognitive assessment' refer to different cognitive abilities and to different perspectives of treatment. If we accept a broad definition, numerous authors and theoretical approaches can be defined as belonging to a cognitive perspective, such as James (1890), Bartlett (1932), and Piaget (e.g. Piaget & Inhelder, 1969). More specifically, the cognitive approach focuses on the analysis of basic cognitive processes, such as perception, attention, memory, language and reasoning. In particular, the Human Information Processing approach, which inspired contemporary cognitive theories, first drew attention to the analysis of such basic processes. One of the main differences between a cognitive and behavioural approach is that the first focuses on the cognitive operations used by the human mind when a subject is engaged in a task, rather than examining general performance. In the study of mental processes, the contemporary view has been influenced not only by approaches that can be strictly defined as psychological, but also by other disciplines such as neuropsychology which studies the relationship between brain structure and cognitive operations, including the effects of brain lesions on cognitive functioning. Much neuropsychology research is in fact conducted on brain-damaged patients. What is defined as *cognitive science* reflects, instead, the particular interest in the study of cognitive abilities from an interdisciplinary point of view, which includes cognitive psychology, neuropsychology, linguistics, artificial intelligence and ergonomics. A cognitive assessment, which is based on cognitive science foundations, is typically aimed at evaluating not only the degree of cognitive abilities but also the presence of basic cognitive processes and how they intervene in the execution of a task. For example, when assessing reasoning abilities, researchers are interested not only in the efficiency of the output, but also in the types of processes involved and those that may be damaged. This approach can also be extended to the assessment of other psychological aspects such as personality and intelligence. For example, in assessment of personality, a cognitive perspective focuses on the cognitive operations which may yield specific psychic states, such as irrational ideas in depression, or impulsive processes in attention deficit or hyperactivity disorders, for example. On the other hand, in assessing intelligence, importance may be placed on identifying tasks which are considered critical for tapping the basic processes of intelligence. For example, when intelligence is assessed by the Raven test (1947), working memory seems to play a crucial role, while the use of other tests may highlight the importance of other components, such as speed of information processing and ability to inhibit irrelevant information.

COGNITIVE ASSESSMENT

A general cognitive approach, as described above, may influence any type of assessment. However, when the object of assessment is a single cognitive ability, such as perception, memory, reasoning or problem-solving etc., the approach acquires more specificity. Detailed procedures of assessment have therefore been designed to investigate the cognitive abilities considered relevant to several tasks. These assessment procedures were either born in the context of experimental and basic research, or, in some cases, represented a genuine effort to design specific psychological tests. Classical psychological tests were also adopted and analysed from the point of view of basic processes. The theoretical and empirical effort of the cognitive approach was greatly supported by studying exceptional individuals presenting specific deficits or strengths. In particular, by studying dissociation cases (which occur when a patient performs normally in one task but is impaired in a second),

cognitive neuropsychology shows which aspect of cognitive activity deserves to be studied, analysed and assessed. For example, theoretical research has highlighted many aspects of memory such as episodic versus semantic, short-term versus long-term, procedural versus declarative, implicit versus explicit, and verbal versus non-verbal memory. A cognitive analysis applied to clinical and educational settings shows which cognitive ability deserves more attention in order to design suitable testing materials. For example, given that implicit memory is a cognitive ability which remains intact in different groups of subjects with memory problems, it is assumed that there is no need to design many standardized tests to study this aspect. Differently, explicit memory which has been shown to be damaged in particular groups, such as old people and pathological subjects, requires the development of many standardized tests. Depending on the cognitive ability of interest, there are different procedures of assessment.

Perception

Many tests have been designed regarding perception aimed at studying whether the subject is able to recognize visual stimuli. They also highlight potential difficulties which, in subjects with good sensory skills, occur in the first stage of information processing (various disorders of visual perception are discussed in Köhler & Moscovitch, 1997). In the field of visual perception, particular success has been attributed to procedures which examine the visuomotor skills; that is, the ability to see a picture and reproduce it, as in many drawing tests used in developmental psychology or with seriously damaged adults. Among these, the Bender (1938) and the VMI (Beery, 1989) tests are very popular.

Attention

It is important to distinguish between different abilities that can be studied by experimental research and so generate different procedures of assessment. One aspect of attention which researchers are interested in concerns the ability to maintain attention focused on a stimulus for a long time (sustained attention). However, many studies (Posner, Rafal, Choate & Vaughan, 1985) have shown interest in the ability to shift attention from one target stimulus to another, or one task to another, which seems to be a crucial index of monitoring ability.

Language

Assessment of language has led to the development of a wide range of testing materials which take into account subjects' age and other aspects of language, such as the prosodic, phonological, lexical, syntactic aspects, sentence processing, discourse processing, and finally, pragmatic aspects of communication. These aspects are assumed to be independent of each other. In this field, the classical distinction between receptive abilities – that is, the ability to understand language – and expressive abilities – that is, the ability to produce language – still remain important.

Memory

As noted above, we can distinguish between different memory systems. It is therefore suggested that different procedures are employed to detect them. In addition to distinctions about the nature of the process, other distinctions which seem relevant from the point of view of analysis of individual differences concern the modality or nature of stimuli, so that memory for colour, faces, words, and meanings are assumed to be widely independent of each other. Recently, particular attention has been directed at assessing semantic and working memory. Semantic memory refers to the organization of human knowledge and can, in some cases, be damaged, while working memory refers to the ability to process information stored in a temporary memory system.

Visuospatial Information Processing and Imagery

In the context of visuospatial and imagery studies, it seems important to assess the visuospatial representations and imagery processes not simply because of the importance of the single components per se but also because they are involved in many aspects of human life. Assessment of these abilities aims to detect how the mind works for spatial representations, and

how images are created and transformed once they have been automatically generated (for a detailed account, see Richardson, 1999).

Reasoning and Problem-Solving

In this case too, there is a need to acknowledge the presence of different components or mental operations which define the reasoning processes. Attention has been directed to some basic operations of reasoning, such as the ability to make associations, to use analogies, make inferences, etc. In other cases, researchers have been interested in studying how subjects perform in a task requiring the combination of many basic operations of reasoning, as in problem-solving. Particular importance has been given to some processes, the so-called executive processes, which refer to the central operations that monitor cognitive abilities. These executive processes partially overlap with the 'metacognitive control processes' which involve planning, anticipating, monitoring and evaluation of results.

COGNITIVE ASSESSMENT IN CLINICAL AND EDUCATIONAL SETTINGS

Generally speaking, cognitive assessment can be applied to any aspect of human life which relies on cognitive processes, so that in pathologies which cannot be strictly defined as cognitive, a cognitive analysis may prove crucial. For example in depression, the cognitive approach focuses directly on negative thoughts to treat depressed patients (Beck, 1976). However, basic cognitive abilities also seem to play a key role in other disorders. For example, there is an increasing number of studies (Goldman & Patricia, 2001) which show that working memory may be damaged in schizophrenic patients, or that depression could be associated with a deficit in visuospatial information processing. In these areas, therefore, a cognitive assessment is adopted for its specific implications which are assumed to be associated to a more general problem. Finally, the use of a cognitive approach is linked to clinical cases in which the cognitive aspect seems to be prevalent, such as disorders of cognitive functioning in children or disorders due to traumatic events which in adulthood cause the loss of specific abilities, such as perception, memory and language. Cognitive assessment usually aims to detect with more specificity and accuracy the elements of dysfunction which occur in a patient. The main aim is also to design and improve treatment procedures to reduce the negative consequences linked to the deficit. In this case, either a deficit-centred logic of training, i.e. a logic focused on the deficit itself, or a 'compensatory' logic, which tries to take advantage of the cognitive resources still available in a subject, may be used. In the learning area, cognitive assessment usually starts with looking at performance indexes and continues on, when the case needs further investigation, to identify which processes the subject may use to perform a task. In this case, the logic of a general cognitive treatment may be more efficient because, differently from a brain-damaged patient, the child can reach significant results due to the greater plasticity of his brain.

FUTURE PERSPECTIVES AND CONCLUSIONS

In the last few years, cognitive assessment has become a very successful approach due to the contributions of different disciplines such as neuropsychology, artificial intelligence, linguistic and developmental psychology. By taking into account such a variety of perspectives, cognitive assessment is moving towards interesting developments. The use of computerized techniques and simulation procedures, the evaluation of the relationship between cognition and its context, the analysis of cognitive potential rather than performance, the refined resolution of cognition into its components are only few of the new areas on which cognitive assessment is recently focusing (for an updated review, see Blankstein & Segal, 2001; Snow & Lohman, 1993). Traditional cognitive assessment and rehabilitation approaches may be also strengthened by a metacognitive logic, in which the rehabilitative or educational work is not simply based on a deficit-centred analysis, but is addressed to identifying strategies which allow the subject to control the mind better and deal more easily with the task. The metacognitive approach refers to the *metacognition construct* which represents knowledge and beliefs about the way the

human mind works and monitors cognitive abilities (see Cornoldi, 1998). This approach, which can still be referred to as cognitive, highlights the importance of assuming a general cognitive view in the assessment and treatment of cognitive abilities compared to a deficit-centred analysis. In fact, the way people think and the procedures they use can also implicate emotional and motivational aspects that could be omitted if a deficit-centred point of view is adopted. It must be noted that if a deficit is a consequence of a severe brain dysfunction, its rehabilitation through a deficit-centred training may be incomplete, making integration with complementary rehabilitation strategies necessary, including the 'compensatory' and metacognitive. In the educational setting, cognitive assessment is the prevalent approach, as it is based on the idea that strengthening the cognitive abilities of a child may lead to the use of correct procedures and, consequently, to better performance. In the assessment of formal learning, the cognitive approach plays a crucial role, shifting the attention of developmental psychologists from the analysis of performance to the procedures a child may use. For example, in mathematical learning, recent developments are focusing on the mental operations a child may use in problem-solving (Lucangeli, Tressoldi & Cendron, 1998), because if the procedures are correct but the result is wrong, the case is less worrying compared with the situation in which the result and selected procedures are both wrong. Also in the analysis of reading processes, attention has been shifted from behavioural indexes (such as reading aloud, silent reading and reading comprehension) to underlying cognitive processes. This perspective has been applied to all formal learning and involves a change in the assessment and educational rehabilitation of learning disabilities.

THEORETICAL PERSPECTIVE: COGNITIVE-BEHAVIOURAL

INTRODUCTION

The cognitive-behavioural approach to psychological assessment has roots in learning theory and cognitive psychology. It is characterized by empirically based, multimethod and multi-informant assessment of behaviours, cognitions, and contemporaneous causal variables in the natural environment. This entry provides an overview of the historical and theoretical foundations of cognitive-behavioural assessment, the strategies and methods used, cultural considerations in its use, and future perspectives.

HISTORICAL AND THEORETICAL FOUNDATIONS

Cognitive-behavioural assessment has been influenced by generations of scholars and by research in multiple disciplines. The concepts and methods of the paradigm are based in applied and experimental behaviour analysis, learning, and cognitive construct systems. Conceptual elements are derived from experimental psychology and the work of behavioural pioneers such as Watson, Pavlov, Hull, Mowrer, and Skinner. The most important contribution from these early researchers is the emphasis on empiricism, which encourages careful observation and precise and frequent measurement of explicitly defined variables. Empiricism remains the supraordinate characteristic of the cognitive-behavioural assessment paradigm.

The methods and foci of behavioural interventions have also played a significant role in the development of cognitive-behavioural assessment. Formal behavioural assessment strategies were initially developed during the proliferation of behaviour therapies in the 1960s, when traditional instruments, which target higher-order variables such as personality traits, were found to be less useful with behavioural methodology's focus on specific, observable behaviours.

Over the next few decades, a wider perspective within the field emerged and the focus of many behaviourists expanded beyond the strictly overt behaviours to include measurement of variables such as sensations, imagery, and psychophysiological functioning (Lazarus, 1973). Theorists such as Bandura, Mischel, Ellis, Mahoney, Meichenbaum, and Beck suggested that cognitions, a person's thoughts, play a significant role in behavioural problems. Although various subparadigms within cognitive-behavioural assessment differ in their emphasis on inferred variables and inner states, all variables targeted in cognitive-behavioural assessment are assumed to be amenable to empirically guided measurement.

BASIC ASSUMPTIONS

Cognitive-behavioural assessment incorporates the following assumptions about the characteristics and causes of behaviour problems (Haynes, 1998; Haynes & O'Brien, 2000): (a) clients often have multiple, related behaviour problems; (b) the importance of any specific behaviour problem differs across clients; (c) behaviour problems have multiple causes that can vary across clients, settings, situations, and time; (d) contemporaneous, social-environmental causes, those occurring closely together in time with behaviour problems, can be important; and (e) cognitions can serve as a causal, moderating, or mediating factor in behaviour problems.

Clients often have multiple, functionally related behaviour problems. For example, a client with marital discord may also be experiencing job difficulties and depressed mood as a result of the marital discord. The client may also increase alcohol consumption to relieve the depressed mood, and the increased alcohol consumption may exacerbate the marital and job difficulties and make it more difficult to handle these difficulties. In addition, the marital discord may have begun as a result of disagreements

with a spouse regarding how to discipline an oppositional child.

The relative importance of behaviour problems may vary across clients. One determines the importance of a behaviour problem in relation to quality of life, or the potential of harm, for the client. For example, two clients who report anxiety in social settings may also report similar problems, such as lack of interest in spending time with friends (social withdrawal), and repetitive negative thoughts (ruminative cognitions). For one client, however, the ruminative cognitions may be more important because thoughts of negative evaluation by co-workers are affecting her job productivity, causing her to lose time from work, and increasing her social withdrawal. For the other client, social withdrawal may be more important because his isolation has fostered depressed mood, ruminative cognitions about his inadequacies, and marital difficulties. For some clients, important variables (such as suicidal behaviours) may occur, but have no identifiable relationships with any social-environmental factors.

Causal relations for clients' problems can vary across clients, across settings and situations, and over time. For example, a lack of interest in social activities may result from a lack of contact with friends while at home, but result from negative social interactions with co-workers at work. Over time, lack of social interactions may become less important while other symptoms, such as lack of sexual activity, become more troublesome for clients.

Finally, contemporaneous social-environmental causal variables often present the primary focus for assessment as cognitive-behavioural therapy can modify these relationships, whereas the original causes of behaviour problems may prove unchangeable. For example, a person may temporarily stop engaging in previously enjoyed activities after the death of a spouse. However, if the person continues to avoid activities after an extended passage of time, the assessor searches for current factors that maintain the avoidance, such as lack of social/dating skills and negative thoughts about future dating possibilities.

ASSESSMENT STRATEGIES

The cognitive-behavioural approach uses assessment strategies that are congruent with its underlying assumptions. Such strategies: (a) are valid measures of important, controllable variables; (b) are sensitive to the dynamic nature of behaviour and causal variables; (c) are sensitive to the conditional nature of behaviour and associated cognitions; (d) capture functional relations; (e) include multiple sources of data; and (f) emphasize observable behaviours and associated cognitions in the natural environment. A central element of cognitive behavioural assessment is hypothesis testing, the formulation and testing of preliminary clinical judgements about a client's behaviour problems and possible causal variables.

Hypothesis-Testing

The cognitive-behavioural assessment paradigm assumes that clinical judgements made about a client's behavioural problem are more likely to be valid if a scholarly, hypothesis-testing approach is adopted. Hypothesis-testing involves the collection and evaluation of data to either support or rule out tentative assumptions about the nature and causes of a client's behaviour problems. Hypotheses are generated very early in the clinical assessment, as early as the referral or pre-interview with the client, and are continuously modified throughout the assessment as new data becomes available. When hypotheses are supported and no new hypotheses are suggested, a treatment strategy is selected. Ongoing assessment of treatment is also part of this strategy, to measure treatment outcome, track treatment effects, and aid in modifying failing treatments.

Validated Instruments

The cognitive-behavioural assessment paradigm also emphasizes the use of validated instruments. Invalid instruments can lead to invalid clinical judgements. However, the validity of an assessment instrument (i.e. the accuracy of the data derived from an instrument) is conditional. Instruments should be validated for samples similar to the client's characteristics (sex, ethnicity), in conditions similar to the target assessment occasion (work vs. home setting), and for purposes congruent with the intended use (screening vs. diagnosis). Clinicians must consider sources of error associated with an instrument (an aspect of the instrument that is

not measuring what it was designed to measure), such as biases in the way data is remembered or observed.

Multiple Sources of Information

Multisource assessment involves the use of multiple (a) informants (teachers, co-workers); (b) methods (self-report questionnaires, analogue observations); (c) instruments (use of more than one informant or questionnaire); (d) assessment occasions (time-series measurement); and (e) contexts and settings (times of the day, different social environments).

There are several important reasons why clinicians should consider multiple sources of information when formulating clinical judgements. First, different sources of information may capture unique aspects of a client's behaviour and its causal variables. For example, information from a co-worker about a client's job difficulties may provide different but equally important information than a self-report questionnaire that asks the client about his or her thoughts or feelings about the job difficulties.

Second, different assessment instruments that use the same method and target the same behavioural problem can also provide unique information about that behavioural problem. For example, several questionnaires may purport to assess 'time-management' skills, yet one may emphasize affective facets of 'time management' while another focuses on behavioural or cognitive facets.

Third, different methods and instruments can capture different modes (e.g. cognitive, affective, motoric, physiological) of a behavioural problem. For example, a semi-structured interview with a client who avoids social situations can provide useful information concerning the affective mode (e.g. depressed mood) of that avoidance. In contrast, a skin conductance test can provide important physiological information (e.g. increased perspiration) concerning the client's social avoidance.

Fourth, each source of information has unique sources of error. For example, information from a teacher about a student's aggressive behaviour can provide useful information but may also reflect the teacher's biases toward the student. Information derived from a self-report depression questionnaire can reflect the client's actual mood state or it may reflect the client's need to present in a socially desirable manner.

Finally, information from different sources can capture behaviours or thoughts of a client in different situations. For example, information from parents about their child's aggressive behaviour at home may differ from information provided by the child's teacher in school. The child may only be aggressive in school but not at home, and in school the child may only be aggressive in certain situations.

Time-Series Measurement

Cognitive-behavioural assessment encourages time-series measurement strategies, which involve frequent measures of important variables over time at regular intervals. This is a useful strategy, given that behaviour and associated cognitions can change rapidly over time. Time-series measurement can (a) capture the dynamic nature of behaviour and cognitions, (b) elucidate functional relations, and (c) evaluate the effects of an intervention. Some examples of time-series measurement include hourly monitoring by hospital staff of a patient's aggressive behaviour to identify environmental triggers and rewards, and the completion of a self-report measure of parent–child interactions prior to weekly treatment sessions to monitor intervention effects.

Time-series measurement can be used to identify patterns of change across time in a client's behaviour problem. For example, a couple with marital difficulties may be asked to self-monitor their daily verbal disagreements for a specified period of time, which is then plotted to visually illustrate change over time. Such data can also help facilitate discussion with the couple about possible triggers for their frequent disagreements. Changes across time in a hypothesized causal variable can also be identified using time-series measurement. For example, to evaluate the hypothesis that certain kinds of verbal interactions between the couple lead to arguments, the couple may be asked to record negative attributions (e.g. explaining the other's behaviour as having negative motives) made during their interactions. Such data can provide information about the changes in negative attributions made that lead to frequent arguments. The hypothesized causal variable can even be manipulated to test different hypotheses when

used with single-case experimental designs (e.g. ABAB reversal designs) as well as to evaluate the effects of treatment.

METHODS OF ASSESSMENT

The cognitive-behavioural assessment paradigm emphasizes the integration of idiographic and nomothetic (combined data of a population or group of individuals) methods of assessment that focus on observable behaviours, cognitions, and their functional relations. Assessment methods most congruent with the underlying assumptions of the paradigm include: (a) naturalistic observation; (b) analogue observation; (c) clinical interview; (d) self-monitoring; (e) questionnaires and other self-report methods; and (f) psychophysiological measurement.

Naturalistic Observation

Naturalistic observation is the systematic observation of behaviour as it occurs in the client's natural setting. It can provide both qualitative and quantitative data on problem behaviours and their causal variables. For example, an assessor may attempt to identify different types of aggressive behaviour (e.g. verbal vs. physical) exhibited by a client (qualitative) or track a prespecified aggressive behaviour over intervals of time to determine frequency, intensity, or duration of that behaviour (quantitative). Naturalistic observation can be carried out either while physically present in the client's environment, or by video recording that is later viewed and evaluated by trained reviewers. However, it can be a difficult and expensive method of assessment, especially for behaviours that are infrequent or socially sensitive. Also, the awareness of being observed may influence the client's behaviour (reactive effects of observation). To minimize these problems, participant observers (individuals already present in the environment, such as hospital staff or spouse) can be used to gather data.

Analogue Observation

Analogue observation involves an artificial setting with environmental manipulations to simulate the natural environment. For example, a parent and child may be asked to discuss a hypothetical problem in the clinic so that the clinician can directly observe their interaction. Analogue observation is a cost-effective strategy that allows the clinician to control and evaluate functional relations, and is particularly useful for low-frequency events, such as partner aggression. Because analogue observation involves contrived settings and is more susceptible to errors associated with assessment reactivity, the generalizability of the data, or the degree to which the data can be extrapolated to real world situations, is sometimes a concern.

Clinical Interview

The clinical interview, perhaps the most widely used method of assessment, can provide valuable information concerning behaviour problems and their functional relations. A distinguishing feature of the cognitive-behavioural interview is the focus on specifying behaviour problems, the identification of associated cognitions, and other important, controllable variables. For example, a child may be interviewed about his or her oppositional behaviour with a focus on specifying type of behaviours (e.g. swearing and throwing objects), antecedent or trigger variables (e.g. request to perform a difficult task by teacher), associated thoughts (e.g. 'Everyone thinks I'm stupid'), modifying variables (e.g. presence of other students), and consequences (e.g. teacher withdraws request). Some potential problems associated with interviews include client and interviewer biases, interviewer characteristics and skill level, degree of client cooperation, and interviewee's cognitive impairments.

Self-Monitoring

Self-monitoring methods involve the client recording specified behaviours, situations, emotions, and/or thoughts. Self-monitoring instruments can be tailored to clients' unique behavioural problems and goals. For example, a client may self-monitor level of anxiety during social activities using a Likert-type rating scale, while recording automatic thoughts associated with the event. Although clients' cognitive limitations, biases, and level of cooperation can bias self-monitoring data, errors can be reduced with clear and detailed instructions, less complex methods, in-vivo practice, and follow-up contacts.

Other Self-Report Methods

Questionnaires, checklists, rating scales, and computer-assisted assessment are other methods of self-report commonly used in cognitive-behavioural assessment. Many methods have been devised to assess the presence, characteristics, frequency, and duration of specific behaviours and cognitions. Such self-report measures are easy to administer and cost-effective; however, consideration must be given to the validity of the measure for its intended purpose.

Psychophysiological Measurement

Psychophysiological measures can provide valid physiological markers of behavioural responses and thoughts. Examples of psychophysiological measures include ambulatory monitoring of cardiovascular reactivity to daily stressors, monitoring of covariation between blood glucose and depressive symptoms, and the measurement of blood pressure and skin conductance to assess physiological arousal to a client's negative self-statements (e.g. 'I'm not as good as my friends'). Some of these methods can be costly to use and require training in the use of technical instruments (Cacioppo & Tassinary, 1990). However, there are many inexpensive and portable devices for the measurement of physiological variables, such as blood pressure and glucose monitors.

PSYCHOMETRIC FOUNDATIONS

Psychometrics, the science of psychological measurement, is the evaluation of data and inferences obtained from assessment instruments. Psychometry plays a central role in cognitive-behavioural assessment, because psychometric evaluation of data helps determine how much confidence can be placed in clinical judgements drawn from the data. More comprehensive discussions of psychometric principles can be found in Cone (1998) and Haynes and O'Brien (2000).

Psychometric Issues Specific to Cognitive-Behavioural Assessment

The application of psychometric principles to cognitive-behavioural assessment is guided by the paradigm's assumptions about the multidetermined, dynamic, and idiographic nature of behaviour. Although assessment can be evaluated on a number of dimensions, some psychometric evaluative dimensions may be less applicable to cognitive-behavioural assessment than others. For example, targeted constructs in cognitive-behavioural assessment, compared to personality assessment, are often lower level, less inferential constructs. Psychometric indices such as internal consistency or factor structure may prove less relevant when applied to lower level constructs.

The validity of any psychometric measurement is conditional – it depends upon the particular assessment goals and settings, the characteristics of the measured variable(s), and the inferences sought. Data from a particular observation instrument may provide a valid estimate of the rate of aggressive behaviours of a child in the classroom, but not provide a valid estimate of these behaviours at home, on the school bus, or at recess. Such data may be validly used to design a classroom intervention, but would not provide a meaningful basis for diagnosis.

Similarly, data obtained in cognitive-behavioural assessment can be accurate but invalid. For example, accurate data may be obtained from analogue observation of a client's social interaction, but the data may display low levels of covariance with the same behaviour measured in natural settings.

The idiographic assessment strategies that are emphasized in cognitive-behavioural assessment also affect the relevance of various dimensions of cognitive-behavioural assessment. Accuracy and content validity are particularly important in idiographic assessment.

Reliability

Reliability refers to the stability or consistency of data derived from repeated administrations of an instrument or procedure across similar situations (temporal consistency), or from the pattern of covariance of elements within an instrument or procedure (internal consistency). In cognitive-behavioural assessment, the assumption that behaviour can change across time and situations complicates the interpretation of reliability coefficients. Coefficients may reflect variability due to true change in the phenomenon of interest as well as measurement error.

Validity

The primary focus of psychometric evaluation is construct validity, the degree to which data and inferences derived from an instrument are representative of the targeted construct. Construct validity represents a meta-judgement that integrates multiple data sources, including indices of reliability, content and criterion validity, and clinical utility (Haynes & O'Brien, 2000).

Content validity reflects the degree to which elements of an assessment instrument are representative of the targeted construct for a particular assessment purpose. Content validity has increased importance in cognitive-behavioural assessment because obtained measures are thought to reflect behaviour or event samples rather than higher order constructs. Thus, one must estimate the degree to which a measure adequately samples the targeted construct (Haynes, Richard & Kubany, 1995).

Applicability and Utility

The utility of an assessment instrument refers to the degree to which it gathers clinically relevant information – i.e. information that increases treatment effectiveness – on particular populations, behaviours, or behaviour disorders. Evaluative dimensions of assessment instrument utility include treatment utility, sensitivity to change, cost effectiveness, usefulness for developing a functional analysis, and incremental validity.

The multimodal, multimethod procedures of cognitive-behavioural assessment have demonstrated considerable empirical utility. However, in settings that emphasize treatment delivery rather than research, some methods may have less than optimal clinical utility, due to the time-consuming nature of methods such as behavioural observation, inadequately trained personnel, and/or financial contingency systems that de-emphasize assessment.

FUTURE PERSPECTIVES

The empirically based cognitive-behavioural assessment paradigm undergoes continual refinement. Changes occurring during the past decade include new strategies for integrating assessment data and new causal models that influence assessment strategies. Although specific advances are too numerous to review here, several broad trends deserve mention. These include (a) an expanding focus of assessment, (b) technological advances in measurement, and (c) a focus on the clinical decision-making process.

An Expanding Focus

Recent changes in cognitive-behavioural assessment reflect an increasing recognition of the complex, dynamic, and multi-determined nature of behaviour. For example, the application of non-linear, dynamical modelling and chaos theory to data analysis allows sophisticated evaluation of complex sequences of behaviour, enhances detection of important functional relationships, and strengthens the inferences from time-series data (Heiby, 1995).

There is an increased focus on the incorporation of cognitive, physiological, social, and systemic variables into case conceptualizations (Koerner & Linehan, 1997). Greater attention is given to understanding the specific cultural context in which a client's behavioural problem occurs, and the validity of instruments and methods used for a client from a particular cultural group. For example, the Culturally Informed Functional Assessment Interview (Tanaka, Matsumi, Seiden & Lam, 1996) has been developed to identify and elaborate the role of specific cultural variables in causal models.

Technological Advances

Computer technology has: (a) facilitated the acquisition of self-report data; (b) permitted more efficient measurement in the natural environment via ambulatory techniques (e.g. hand-held computers); (c) enhanced the collection, reduction and analysis of time-series data; and (d) increased the efficiency and objectivity of clinical judgements by allowing computerized synthesis of data and hypotheses (Kazdin, 1998).

Increased Focus on Clinical Decision-Making

Accompanying the broadening scope of cognitive-behavioural assessment is an emphasis on the

development of more systematic and objective methods of case conceptualization. Clinical case conceptualization aims to identify important causal variables and integrate these into a model that allows the formulation of optimal intervention decisions. Visual systems for integrating assessment data, and guiding clinical decision-making, have undergone refinements in the past decade (Haynes, 1992; Haynes & O'Brien, 1990; Nezu & Nezu, 1993).

CONCLUSIONS

This entry presented a brief overview of the conceptual premises, characteristics, and methods of the cognitive-behavioural assessment paradigm. Cognitive-behavioural assessment is a dynamic and evolving paradigm that encompasses many subparadigms. The methodological diversity of the approach reflects the influences of experimental, learning, and cognitive conceptual systems. A supraordinate characteristic of cognitive-behavioural assessment is its empirical orientation.

Assumptions that affect the goals and methods of cognitive-behavioural assessment include emphases on individual differences, contemporaneous, social-environmental causal models, and the dynamic, multidetermined nature of behaviour. Cognitive processes are addressed as causal and mediating variables of behaviour problems. Important strategies in cognitive-behavioural assessment include the use of multisource, well-validated measures, time-series measurement, and an idiographic, functional approach to assessment. A scholarly, hypothesis-testing approach to clinical case formulation is a cornerstone of the paradigm.

THEORETICAL PERSPECTIVE: CONSTRUCTIVISM

INTRODUCTION

An assessment strategy might be classified as constructivist to the extent that it (a) elucidates 'local', as opposed to 'universal', meanings and practices in individuals or social groups, (b) focuses upon 'provisional', rather than 'essential', and unchanging patterns of meaning construction, (c) considers knowledge to be the production of social and personal processes of meaning-making, and (d) is more concerned with the viability or pragmatic utility of its application, than with its validity, per se (Popkinghorne, 1992). This emphasis on local, provisional, and pragmatic assessment of (inter)personal meanings can be illustrated by a closer consideration of two core techniques associated with a constructivist approach, each of which encompasses many different variations. These include *repertory grid technique*, which focuses on the content and structure of people's construct systems, and the *analysis of personal narratives* in spoken or written 'text', which reveals the changing processes by which people create meaningful stories of their experience.

REPERTORY GRID TECHNIQUE

Developed within personal construct theory, repertory grid technique represents a widely used method for studying personal and interpersonal systems of meaning. Because of their flexibility, repertory grids (or *repgrids*) have been used in literally thousands of studies of a broad variety of topics, ranging from the shared perceptions that constitute an organization's unique 'culture' to the naïve understandings of school children about physical science concepts (Fransella and Bannister, 1977). However, the most common application of grids has been in the clinical area, where they have been used to study such issues as the body images of women struggling with eating disorders and attitudes toward alternative careers held by clients in vocational counselling.

The 'reptest' was initially designed by George Kelly (1955), the author of personal construct theory, as a means of assessing the content and structure of an individual's repertory of role constructs – the unique system of interconnected meanings that define his or her perceived relationships to others. In its most common form, the reptest requires the respondent to compare and contrast successive sets of three significant people (e.g. my spouse, my father, and myself), and formulate some important way in which two of the figures are alike, and different from the third. For example, if prompted with the above triad, a person might respond, 'Well, my father and husband tend to be very *conventional* people, whereas I'm more *rebellious*.' This basic dimension, *conventional vs. rebellious*, would then be considered one of the significant themes or constructs that the person uses to organize, interpret, and approach the social world, and to define his or her role in it. By presenting the respondent with a large number of clinically significant 'elements' (e.g. a previous romantic partner, best friend, a disliked person, one's ideal self), the reptest elicits a broad sampling of the personal constructs that constitute the person's outlook on life and perceived alternatives. These constructs can then be interpreted clinically, used as the basis for further interviewing of the respondent, or coded using any of a number of reliable systems of content analysis, conducted either manually or with available computer programs (Neimeyer, 1993).

Although the analysis of construct content often is revealing, most users prefer to extend the method beyond the simple elicitation of constructs by prompting the respondent subsequently to rate or rank each of the elements (e.g. people) on the resulting construct dimensions. For example, a respondent might generate a set of 15 constructs, on which 10 important elements (e.g. my mother, employer, self, partner) could be rated, yielding a matrix of 150 specific ratings

that would then be amenable to a wide range of analyses. Although the repgrid was originally devised as an interview-based or paper-and-pencil measure, contemporary users typically rely on any of a number of computer programs for their elicitation and analysis, such as the popular *WebGrid III* program available via the Internet. Although analysis of the grid can focus on simple element ratings (e.g. observing that the respondent views herself as *independent*, *rebellious*, *driven by fear*, etc. on a sample of her personal constructs), it is often more helpful to conduct a comprehensive analysis of the grid to discern larger patterns. This might involve correlating and factor analysing the matrix of ratings to see at a glance which constructs 'go together' for the respondent (e.g. *independence* is associated with being *secure*, whereas *dependence* implies *vulnerability to hurt*), or to learn the people with whom the client most and least identifies. These linkages among constructs often suggest why people remain 'stuck' in symptomatic patterns, as when a client resists becoming more *assertive* instead of *passive*, because the former is associated with being *rejected* as opposed to *loved*. Similarly, patterns of identification among elements in a grid can be clinically informative, with some of these (e.g. degree of correlation between actual self and ideal self) providing useful indices of progress in psychotherapy. At the most general structural level, grids can be useful in identifying how 'tightly' or 'loosely' a given person's meaning system is organized, as revealed, for example, by the average degree of correlation among the constructs that comprise it. Clinically, overly 'tight' systems, in which most constructs are closely linked, such that changes in one imply alterations in many others, have been associated with resistance to change in psychotherapy. Conversely, very loose systems might signal that the individual is having a great deal of difficulty in developing a coherent view of the social world, a factor that has been associated with the heightened despair and perturbation preceding high-risk suicide attempts.

Although repgrids are most commonly used to assess the idiosyncratic content and structure of an individual's construct systems, they have also been used to evaluate how members of families and groups view one another, as well as how they converge or diverge in their outlooks. For example, convergence in the content, application, and structure of personal constructs has been found to predict successful intimate relationships, whereas inability to construct a common reality has been implicated in relationship breakdown and failure. In keeping with a constructivist philosophy, however, such meaning systems are viewed as 'moving targets', which require ongoing assessment, particularly in the shifting context of psychotherapy. Assessment methods having some affinity to grid technique include *laddering technique*, which elicits the higher-order value implications of the respondent's constructs of behaviours and social roles (Neimeyer, Anderson & Stockton, 2001), and the *self-confrontation method*, which evaluates an individual's sense of agency and communion with others through an analysis of important life events. A common feature of these methods is their focus on *personal structure*, viewing meaning in systemic terms that can be depicted visually to enhance its comprehension and discussion by clients and therapists.

NARRATIVE ASSESSMENT

Narrative psychologists believe that the structures and elements of which stories are composed act to direct our thought processes. Instead of viewing logic as the guiding force behind information processing, they view people as organizing life events into unique plot structures and creating themes that give them significance. This quest for meaning is especially evident in people's attempts to develop self-narratives that give them a sense of identity and coherence, and that allow them to share their experiences with others (Neimeyer & Levitt, 2001). This 'storying' of complex life experiences draws on the distinctive language, scripts, and symbols derived from different cultures and traditions, as well as the unique life histories of their individual authors. The rapid development of this narrative perspective over the last 20 years owes partly to its broad relevance across cognitive, developmental, and clinical areas of research. However, psychotherapy researchers have been particularly active in developing methods to assess the style and substance of clients' stories, whether told within the therapeutic hour or in subsequent research interviews about their therapy or their lives.

The *Narrative Process Coding System* illustrates the use of constructivist methods to assess the topical and thematic shifts that characterize client accounts of their experience (Angus, Levitt & Hardtke, 1999). First, an investigator using the system segments the dialogue of a transcribed therapy session into topic units that are identified through shifts in protagonists and themes. For instance, a client may begin a session by discussing a recent trip to Florida and then shift to an examination of disappointing family vacations in childhood. The identification of such topic segments can allow researchers to consider how themes are maintained or changed through discussion and how the interpersonal psychotherapeutic process can act to facilitate narrative development. Second, the researcher codes these topic segments into one of three narrative processes. *External* narrative sequences are dominated by event description. An account of a vacation itinerary would be an example of this narrative type. *Internal* narrative sequences focus upon emotional and experiential states. A description of the storyteller's awe or uneasiness at first glimpsing the ocean would exemplify this narrative process. Finally, *reflexive* narrative sequences entail analysis and interpretation of events and internal reactions in order to understand their significance. An exploration of the meaning of relaxation in one's life would be classified as reflexive.

Through the assessment of narrative processes, researchers can study how changes in the client's storytelling about life events are evidenced in therapy. For example, investigators have found that experiential therapists tend to shift discourse from external event descriptions toward internal and reflexive processes to promote self-exploration and meaning-making, while clients tend to shift into a more external process, to integrate their therapeutic insights into their daily life experiences. Likewise, narrative process assessment of various types of treatment could suggest what forms of client processing are associated with more favourable outcomes in different forms of therapy. For example, prompting clients toward an external storytelling, communicating childhood events and experiences, seems to facilitate progress in psychodynamic therapy, whereas encouraging a more reflexive, interpretive style appears to promote more rapid gains in a cognitive treatment (Angus et al., 1999).

Assessment of the narrative forms and structures of different clients has also begun to shed light on distinctive features in the themes and style of their self-narratives. A schizotypic client, for instance, might display a fragmentary, poorly elaborated narrative style in relating events of his life, in a way that gives few clues about his internal responses to the stories he tells. Such research holds promise for clarifying difficulties in narrative production in different diagnostic groups, and for tracking their change over therapy toward richer and more communicable accounts of their experience.

Other constructivist methods for assessing different dimensions of clients' self-narratives include various *content scales* for coding the extent to which people feel like 'origins' of life choices or 'pawns' of fate, as well as their level of 'cognitive anxiety' associated with the diagnosis of serious illness (Gottshalk, Lolas & Viney, 1986). Another method, the *Narrative Assessment Interview* involves asking open-ended questions inviting the client's self-description from internal and external perspectives at the outset and termination of therapy. Systematic coding of the responses can yield a clear depiction of client change over treatment, while permitting clients to convey this change in their own words, rather than having to 'translate' their meanings into the sometimes alien language of the assessor.

FUTURE PERSPECTIVES AND CONCLUSIONS

Although constructivist assessment methods have a history that dates at least back to the 1950s, they are currently enjoying a period of rapid development (Neimeyer & Raskin, 2000). In part, this reflects the growing popularity of constructivist and narrative approaches to psychological theory, with their attendant focus on the unique meaning-making processes of individuals and social groups. In part, their proliferation also reflects the continued elaboration of human science methodology, which has developed along both quantitative lines (as reflected in the range of computer programs for administering and analysing repertory grids) and qualitative lines (as evidenced in thematic approaches to narrative analysis). Nonetheless, users of constructivist assessment methods confront problems

as well as prospects, as they consider how to evaluate the validity and reliability of measures that respect the individuality, complexity, and mutability of the meaning-making processes of their subjects. Preliminary studies of the psychometric adequacy of these methods are encouraging, however, suggesting that the further refinement and application of constructivist assessment will contribute to a more adequate psychological science and practice in the future.

THEORETICAL PERSPECTIVE: PSYCHOANALYTIC

INTRODUCTION

Psychoanalytic theories of behaviour embrace a diversity of views that can be grouped into four main lines of thought: drive theory, which focuses primarily on basic needs of the individual and how these needs are channelled and expressed; ego theory, which stresses the nature and adequacy of the coping resources that people bring to bear in dealing with life situations; object relations theory, which emphasizes the representations people form in their minds of the characteristics of other people; and self-psychology, which attends to how people differentiate themselves from others and develop a sense of agency, authenticity, and self-esteem (see Pine, 1990). Despite many differences among them, these threads of psychoanalytic thought share three common premises, each of which has been confirmed by empirical research findings (see Masling, 1983, 1984; Westen & Gabbard, 1999): (a) unconscious mental processes, including thoughts, feelings, and motivations that exist outside of conscious awareness and influence an individual's personality characteristics and action tendencies; (b) a dynamic interplay between conflicting attitudes that generate anxiety leads in all people to defensive manoeuvres intended to reduce this anxiety; and (c) developmental experiences play an important role in shaping abiding personality characteristics and patterns of interpersonal relatedness.

Accordingly, psychological assessment from a psychoanalytic perspective serves the purpose of

elucidating aspects of personality structure and personality dynamics in ways that clarify the role of drives, conflict and defence, and object representations in shaping how people are likely to think, feel, and act. Assessment information framed in this way assists dynamically oriented clinicians in formulating the problems, diagnostic status, and treatment needs of patients they see and guides them in planning and conducting whatever psychotherapy they provide (see Blatt & Ford, 1994; Shectman & Smith, 1984). Familiarity with this psychoanalytic perspective on assessment also gives psychologists direction in their selection of assessment procedures and the manner in which they interpret the data they obtain. This impact of psychoanalytic theory on the selection of assessment procedures and their utilization in differential diagnosis and treatment planning can be traced to the seminal work of Rapaport, Gill, and Schafer (1968) and has subsequently been reflected in numerous other publications (see Weiner, 1983).

ASSESSING PERSONALITY STRUCTURE

Personality structure comprises a broad range of fairly stable characteristics and orientations of individuals that lead them to conduct themselves in certain ways. Most important among these persistent tendencies and abiding dispositions from a psychoanalytic perspective is a person's coping style, particularly with respect to his or her preferred defence mechanisms. Strictly defined, defence mechanisms constitute mental operations or overt behaviours undertaken without conscious awareness to minimize or avoid the experience of anxiety, as in attributing one's own unacceptable attitudes to someone else (projection) or having to repeat a useless ritual in order to feel comfortable (undoing). As elaborated in the work of Schafer (1954) and Cramer (2000), defence preference information emerging from psychological assessment can facilitate differential diagnosis, as in recognizing excessive reliance on projection as a likely indicator of paranoid tendencies and pervasive undoing as a clue to obsessive-compulsive disorder.

Appropriately selected and interpreted psychological assessment methods also help to identify the adequacy as well as the nature of an individual's defensive style and preferred ways of coping with stress. Particularly important in this respect is the utility of psychodiagnostic testing in measuring the maturity of an individual's personality organization. Test-based distinctions among neurotic, borderline, and psychotic levels of organization provide valuable information for differential diagnosis and many key aspects of treatment planning (see Lerner, 1998; McWilliams, 1994; Silverstein, 1999).

The capacity of people to cope with stressful situations without becoming unduly upset by them, as revealed by assessment data, provides a general index of ego strength that can contribute to drawing conclusions and making recommendations in a wide range of contexts. Finally of note, psychodiagnostic indices of ego strength capture the adequacy both of defences erected against conflict-induced anxiety and of resources existing in the conflict-free sphere of ego operations. Hence, a psychoanalytic focus on assessing coping capacities helps direct attention not only to an individual's psychological limitations and maladaptive tendencies, but also to his or her personality assets and admirable qualities as well.

ASSESSING PERSONALITY DYNAMICS

Personality dynamics refer to the nature of people as defined by the underlying needs, attitudes, conflicts, and concerns that influence them to think, feel, and act in certain ways in certain circumstances. These underlying dynamic influences on behaviour interact with structural aspects of personality functioning to determine what people actually say and do in their daily lives. In this interaction, however, the nature and adequacy of people's coping style is usually more directly apparent from their behaviour than from their inner life, which is often expressed indirectly in derivative manifestations of underlying psychic phenomena. For this reason, psychoanalytic perspectives have been singularly significant in psychodiagnostic assessment for fostering the utilization of psychological tests to illuminate underlying personality dynamics that by their nature are less obvious and less easily detectable than aspects of personality structure.

For example, numerous widely used personality assessment instruments designed to draw

inferences indirectly on the basis of how people perform on various tasks, rather than directly on the basis of how they describe themselves, include scales and guidelines for measuring needs for dependency, achievement, dominance, intimacy, and various other drive states of the individual. These measures can be used to identify underlying hostile, resentful, loving, collaborative, and other attitudes toward significant other figures in a person's life, or underlying derogatory, aggrandizing, and other attitudes toward oneself, all of which reveal the kinds of object representations a person has formed. Likewise, indirect personality assessment can identify concerns about sexual identity, interpersonal humiliation, loss of self-control, and other underlying sources of anxiety that may not be directly apparent or within a person's conscious awareness but can be accurately and usefully formulated within a psychoanalytic perspective.

DEVELOPMENT OF INSTRUMENTS

As already implied, psychoanalytic perspectives have influenced psychological assessment methods not by fostering the development of new instruments, but by enriching the ways in which existing measures can be used and interpreted. Perhaps the most notable exception in this regard is Blum's (1950) Blacky Pictures, on which respondents tell stories to cartoon pictures depicting the doggy Blacky and drawn with the specific intent of capturing such psychoanalytic developmental phenomena as oral eroticism, oedipal concerns, and castration anxiety. However, neither this measure nor any like it has ever found widespread use in actual practice. On the other hand, four types of relatively unstructured performance-based measures have shown considerable potential for tapping underlying personality dynamics and have lent themselves well to psychodynamic formulations of the test process and of specific test indices focused on psychoanalytic concepts. These four types of measures include (a) inkblot methods, as exemplified mainly by the Rorschach; (b) story telling methods, as first formalized with the Thematic Apperception Test and subsequently expanded to include such other commonly used methods as the Children's Apperception Test, the Roberts Apperception Test, and the Tell Me a Story Test; (c) figure drawing methods, of which the best known are the Draw-a-Person, the House–Tree–Person, and the Kinetic Family Drawings; and (d) sentence completion methods, as illustrated by the Loevinger Sentence Completion Test and the Rotter Incomplete Sentences Blank.

FUTURE PERSPECTIVES AND CONCLUSIONS

As is the case in describing personality functions or the process of psychotherapy, psychoanalytic perspectives bring to psychological assessment a breadth of formulation and a depth of understanding that could not otherwise be achieved. It is by looking beneath the surface of human behaviour, by seeking to know not only what is apparent but also what appearances may reflect or signify, that psychodynamic approaches to assessment can grasp why people act as they do and how they are likely to act in the future. There is sometimes a tendency in science to become enthralled with new ideas and regard older ideas as antiquated and obsolete. Psychoanalytic thinking, despite its voluminous literature and constant fresh outpouring of reconceptualizations and new directions (see Pine, 1998), is subject to being demeaned for its longevity and denigrated as a 19th century relic, as if Freud's Vienna marked the end of its development. Solid in substance and invigorated with fresh ideas, however, psychoanalytic perspectives seem destined to continue enriching psychological assessment for many years to come.

THEORETICAL PERSPECTIVE: PSYCHOLOGICAL BEHAVIOURISM

INTRODUCTION

Behaviourism, with its goal of establishing the general theory of conditioning, has never had much of a connection to the traditional field of psychological measurement. Psychological measurement has a contrasting goal, that of dealing with individual differences. Furthermore, as Spence (1944) pointed out, behaviourism deals with stimulus-response laws, where the independent variables are the stimulus manipulations that affect the dependent variable, behaviour. Predictive tests, in contrast, deal with response–response laws where the first response (a test result) is related to the second response (the individual's predicted performance). These R-R laws are not causal as S-R laws are. Skinner's radical behaviourism has added to the reasons for ignoring the field of psychological measurement by taking the position that the individual's performance on tests can give no information about the individual's behaviour (1969: 77–78).

Psychological behaviourism has differed from the start, making behavioural analyses of existing psychological tests and projecting assessment in the context of a behavioural therapy (Staats, 1963).

> [A] rationale for [behavior therapy] will also have to include some method for the *assessment of behavior*. In order to discover the behavioral deficiencies, the required changes in the reinforcing system, the circumstances in which stimulus control is absent, and so on, evaluational techniques in these respects may have to be devised. [It is necessary] ... to determine such facts for the individual prior to beginning the learning program of treatment. Such assessment might take a form similar to some of the psychological tests already in use ... [However,] a general learning rationale for the behavior disorders and treatment will itself suggest techniques of assessment. (Staats, 1963: 508–509, italics added)

Silva (1993) has described the psychological behaviourism contribution as 'pioneering' with respect to founding the field of behavioural assessment. For in 1963 there were no other radical behaviourism or social learning theory that suggested the new behavioural assessment developments. However, later researchers (for example, Mischel, 1968; Kanfer & Saslow, 1965) used the psychological behaviourism projection of behavioural assessment within a *radical behaviourism* approach, thereby confining the development of the field to the principles of reinforcement, direct measurement of behaviours, and the rejection of psychological tests.

Psychological behaviourism, however, has continued to develop its position that there

should be a unification of traditional psychological assessment with behavioural analysis (see Burns, 1980; Fernández-Ballesteros & Staats, 1992; Evans, 1985, 1986; Staats, 1975, 1996).

PSYCHOLOGICAL BEHAVIOURISM, PERSONALITY, AND PSYCHOLOGICAL ASSESSMENT

Traditional (including radical) behaviourism could not connect to the field of psychological measurement because it lacked a theory of individual differences (personality) with an empirical-methodological arm. Psychological behaviourism has established a new approach that, while entirely consisting of behavioural principles and methods, nevertheless creates such a personality theory (see especially Staats, 1963, 1968, 1971, 1975, 1996). The basic conception is that at birth the child begins to learn complex repertoires of behaviour. And that changes the child. For example, when a two-year-old child has learned a rudimentary language repertoire the child is changed very basically, as in the child's characteristics of learning. To illustrate, a child with language can learn to count via instruction (see Staats, 1968). This type of training is not possible with a pre-verbal child.

There are thus individual differences among children in learning ability on the basis of repertoires that they have already learned. Thus, on the one hand, the repertoires are an effect since learning trials produced them. On the other hand the repertoires are a cause. The child who has them is capable of learning that a child without the repertoires is not. The learned repertoire in such a case is both a cause and an effect.

The psychological behaviourism position generally is that individual differences in behaviour in the same situation are due to previously learned basic behavioural repertoires (BBRs) in three general areas: language-cognitive, emotional-motivational, and sensory-motor. The psychological behaviourism theory is that those BBRs constitute personality. The phenomena of personality are explained by the basic behavioural repertoires. As additional examples, people have behavioural characteristics that are general across situations, and show continuity over time as well, because of their learned BBRs.

PSYCHOLOGICAL ASSESSMENT

Psychological behaviourism states that psychological assessment instruments measure the individual's BBRs. As one example, PB has analysed many items on intelligence tests that measure aspects of the child's language repertoires. To illustrate, the child must be able to respond to verbal instructions to succeed on most items. Other items assess the extent of the child's verbal labelling repertoire (i.e. vocabulary), with increasing refinement as age increases (as with words dealing with length and number). There are wide individual differences in the language repertoires children have learned and hence in how well they will do on intelligence tests.

Following the theory, if intelligence consists of learned repertoires then it should be possible to increase intelligence through training. We (Staats & Burns, 1981) tested this in one study in which four-year-old children were given training in writing the letters of the alphabet (which yields skills in the sensory-motor repertoire). When these children were later given the WPPSI (Wechsler, 1967) they did significantly better on the Geometric Design and the Mazes tests (ordinarily thought to measure different mental abilities) than children without the letter-writing experience. The training had given the children basic repertoire elements relevant to various other intellective performances.

With respect to the emotional-motivational repertoire PB has shown that values, interest, and attitude tests are composed of items that measure emotional response to different types of stimuli (see Staats, 1996). In one study (Staats & Burns, 1981), it was shown that people measuring high in religious values learned an approach response to religious words more quickly than subjects low in religious values. But when an avoidance response had to be learned to such words, people with high religious values learned more slowly than people with low religious values. This showed that religious values consist of emotional responses that individuals have learned to religious stimuli and differences in this personality characteristic affect the way the individuals behave and learn. In another study it was shown that being high or low in a vocational interest, a personality difference, determined two groups' choice behaviours. Attitudes toward racial groups also have been shown to involve emotional responses that have

been conditioned to racial features and names (see Staats, 1996). The commonality in principle in values, interest, and attitude tests shows how the personality theory unifies personality concepts and the tests used to measure personality. (For additional PB works in psychological assessment see Burns, 1980; Carrillo, Rojo & Staats, 1996; Evans, 1985, 1986; Fernández-Ballesteros & Staats, 1992; Heiby, 1989.)

Prediction and Test Construction Methodology

One of the things a theory of psychological assessment should provide is an understanding of what the field does and what kind of knowledge is produced by the field's products. For example, PB explains why psychological testing knowledge can provide prediction of behaviour but cannot provide knowledge by which to change the individual's behaviour (personality) characteristics.

Let us start with prediction. In constructing intelligence tests, for example, items are selected that some children can answer correctly and other children cannot. Then the items are evaluated for the extent to which they predict children's success in school, and those that predict are selected for use. The general belief, however, is that IQ tests measure some biological process, quality, or structure within the child – intelligence – that determines the ability of the child to learn in school. That is why the tests are thought to predict school success.

The PB explanation, in contrast, is that *the intelligence test measures BBRs the child needs to be able to learn in school*. The criterion that an item, to be included on an intelligence test, must predict school success ensures that the item is measuring a part of a BBR that is necessary for the child to learn in school. Similarly, when a group of interest test items are shown to be characteristic of a particular occupational group this reveals an important aspect of the emotional-motivational repertoire (likes and dislikes) of those individuals. That is the reason why any individual with the same emotional repertoire will be happy on the job; that is, will have positive emotions elicited by the stimuli in that occupation, will find rewards on the job, and will be drawn to activities that enhance job skills and success. Interest tests predict successful occupational behaviour because they measure emotional response to occupationally relevant stimuli, as we have shown (Staats, Gross, Guay & Carlson, 1973), not because of some mental trait called an interest.

Because of their construction psychological tests provide prediction of later behaviour. But to be able to control – that is, effect – that later behaviour requires (1) that the basic behavioural repertoires that yield that behaviour are known as well as (2) the learning conditions that determine those BBRs. Let us take the intelligence test as an example. The knowledge of a child's IQ score provides improved prediction, but not control on the child's performance (behaviour) in school. However, by identifying the BBRs that the intelligence test measures, it is possible to use the test to detect what BBRs a child has as well as what BBRs the child lacks. Using the knowledge of how to train the child in the deficit BBRs it is then possible to improve the child's school performance. More generally, the PB psychological assessment theory, its analysis of testing instruments, and its training procedures can provide knowledge by which to effect behavioural outcomes. As another example, take the Geometric Design and Mazes tests of the WPPSI. If the child's score is low on these tests that says the child lacks the necessary BBRs. The psychological behaviourism analysis states that training the child to write the letters of the alphabet provide the necessary BBRs and thereby raise the child's intelligence scores on these two tests. The research results verify this.

If we had that type of knowledge for the various psychological tests in existence then it would be possible to do something about the individual differences they measure. That would apply to the personality repertoires (BBRs) that compose sociability, extraversion, neuroticism, depression, and paranoid personality. With respect to intelligence tests a partial analysis has been made with respect to what intelligence is and how it is learned. What is needed is the complete analysis of and research on the BBRs that compose children's intelligence, so problems of intelligence could be prevented and treated.

Organic Determinants of Individual Differences

Does this mean that PB takes the position that behaviour and personality is entirely determined by learning? I can answer this simply: no. The

organic state of the individual is important during the learning of the BBRs. If there is some organic reason that reduces the individual's ability to learn, then even with normal learning conditions there will be a decrement in the formation of the BBRs. Moreover, once the BBRs have been learned organic trauma may delete them or distort them. In either case, when the individual encounters later life situations they will have a deficient or distorted set of BBRs from which elements of the individual's behaviour can be selected. So organic conditions can be causes of behaviour, in several ways.

Environmental Determinants of Individual Differences

The psychological behaviourism theory of personality states that the environment plays two roles. It is the learning experiences of the environment that lead to the formation of the BBRs. But the environment also plays a role at the time of behaving. A person may have learned a repertoire of aggressive behaviours, for example. But elements of the repertoire will only be called out in some situations. Individual differences in behaviour can result because individuals with similar BBRs are confronted with different life situations (environments).

FUTURE PERSPECTIVES AND CONCLUSIONS

As future perspectives the psychological behaviourism theory provides a wide-ranging programme of study for further development of the field of psychological assessment.

Analysis of Psychological Assessment's Test Instruments

Psychological behaviourism has analysed various psychological tests – for example, intelligence – in a prototypical way. The value of such analyses have been shown, as in training children to be more intelligent. But the purview that this work opens is vast. For there are many tests to be analysed in terms of the basic personality repertoires they measure. A major future perspective, thus, consists of the call for studies to analyse in specific detail the basic behavioural repertoires that compose the major tests in the field.

Test Construction

Psychological behaviourism in its present form provides a foundation for the construction of new types of tests. One of the basic behavioural repertoires that is involved in intelligence and other tests is that of language. Psychological behaviourism has analysed and researched the learning of the sub-repertoires of which language is composed. Those analyses could form the basis for constructing an intelligence test for children. Other similar developments are suggested.

Behavioural Research: Connecting to Psychology and Establishing Control

Fernández-Ballesteros (1994) has called for relating psychological assessment to other fields of psychology. At present the focus is on measurement, not on study of the causes of what is measured. But construction of tests that provide knowledge by which to change personality or behaviour requires work beyond that of measurement. It requires specification of what is measured, what causes what is measured, and how what is measured affects behaviour. Psychological behaviourism says that intelligence consists of learned personality repertoires that make connections to fields concerned with learning and behaviour. Establishing those connections can give psychological assessment the power not only to predict but also to affect that which is predicted. A perspective of psychological behaviourism is to further that major development.

Assessment Instruments and Basic Personality Research

Another avenue for unifying psychological assessment and basic psychology has been projected. To illustrate, psychological behaviourism's general theory of emotion includes the principle that emotions elicited from different sources algebraically add to each other in producing an emotional state. If the emotions are both positive or negative, there is a more intense emotional state. But when a positive emotion is added to a negative the emotional state is less intense. Jesus Carrillo has suggested testing this using a test that measures positive and negative emotion from experience and from thoughts, with a depression inventory

measuring the emotional state. He, Nieves Rojo, and the author have data that shows the productivity of this approach. Peter Staats, myself, and Hamid Hekmat (2001) have researched the principle using an integration of psychological assessment and experimental psychology. The two sources of emotion were (1) a positive or negative placebo and (2) high or low anxiety as measured on a pain anxiety scale. The dependent variable was extent of pain in the cold pressor task. Our results showed subjects with two sources of negative emotion had greater pain than subjects with two positive sources, with subjects with mixed positive and negative sources falling in between.

These are examples of how psychological behaviourism suggests a programme for using test instruments in the study of psychological processes.

The Disunity of Psychological Assessment: A Programme for Unification

The fields of personality and psychological assessment constitute a chaos of highly diverse studies. There are many different personality theories, set forth in different theory languages, and ordinarily considered separately, with no systematic attempt at integration. The same is true in psychological assessment, where there are innumerable tests whose relationships are unknown, even when they overlap in items.

These tests can be analysed in terms of the BBRs their items measure. Such analysis can define those tests in terms that relate and organize them and thereby unify the field (see Staats & Burns, 1981). Such analyses would also yield knowledge for constructing tests that would measure the BBRs without redundancy. The psychological behaviourism goal of unification calls for many works of various kinds.

Clinical Treatment, Assessment, and Evaluation

Fernández-Ballesteros and Staats (1992) have constructed a model that relates assessment, treatment, and evaluation within psychological behaviourism. There are many suggestions for works to be conducted within this model (see also Eifert, Evans & McKendrick, 1990).

Conclusion

Psychological behaviourism is a broad overarching theory that includes a unification of psychological assessment methods and instruments with principles and methodology of a behavioural theory of personality. This theory suggests various new avenues of development and research that will define psychological assessment and relate it to the other fields of psychology.

THEORETICAL PERSPECTIVE: PSYCHOMETRICS

INTRODUCTION

Human behaviour is enormously variable, depending on the inner state of a person, the demands and opportunities of a situation, and in dependence on a person's individual style of living, and on her/his interests, abilities, values, and motives. 'Psychological assessment' denotes the universe of systematic, scientifically based methods for describing, recording or interpreting a person's behaviour – provided that a method meets defined psychometric criteria, especially of reliability and validity. In this contribution basic concepts and psychometric methods employed in developing, evaluating and applying assessment methods are introduced.

MENTAL MEASUREMENT

The variations in behaviour and experience, which are captured in an assessment method, differ in the kind and source of psychological data accessed. These may include biographical information (like school records or employment history information), behaviour traces (products of a person's behaviour, like drawings), direct behaviour observation, behaviour ratings, segments of expressive behaviour (like handwriting or style of emotional expression in a person's face), so-called projective techniques (highly unstructured visual or other stimulus material, which a person is invited to interpret), interview data, questionnaire responses, so-called objective tests, or psychophysiological data. In this sense, psychological assessment encompasses a wide spectrum of methods, with 'tests' being but one type of method. As a technical term, '(objective) test' refers to a sample of items, questions, problems or the like chosen to sample representatively a presumed universe of items, questions or problems indicative of the trait or state to be assessed (Pawlik, 2000: 382). The literature referenced in the section 'Psychometric Assessment Theories', introduces these assessment sources in all the necessary detail.

While the choice of an assessment methodology will depend on the nature of the assessment problem under study, the heuristic goals of assessment can be described independent of the method chosen. This goal can either be descriptive, prognostic, explanatory, or decision-oriented. Purely descriptive assessment is a relatively infrequent exception, where the assessment is conducted with the sole purpose of describing the current behavioural state of a person. Much more

frequent are assessments subserving a prognostic or explanatory goal. In the first case the assessment is conducted to predict the person's behaviour, state of feeling etc., at a future occasion or in another setting. Examples are psychological tests administered to predict a person's success in a training programme or under psychotherapy. Extending assessment results in the opposite direction of time is called explanatory: to infer from a person's assessment results her/his psychological state at an earlier stage of development or under past situational conditions. For most practical purposes, psychological assessment is – primarily or additionally – decision-oriented. That is to say that the assessment results are employed to facilitate or improve decisions among alternative courses of action or treatment. These may refer to different types of educational or professional training, to different methods of psychological therapy, to alternative vocational choices, or the like.

Irrespective of the heuristic goal, assessment methods have to meet stringent criteria of accuracy (reliability) and validity. To this end, formal (i.e. mathematical–statistical) theories of measurement have been developed for the construction and the quality control of assessment methods. 'Psychometrics' is the branch of psychological methodology that comprises these theories and resulting methods for developing and evaluating assessment methods. In this context 'measurement' simply refers to a method of mapping variations in behaviour or experience onto a chosen number system. Different levels of measurement are distinguished depending on the rules and prerequisites chosen for this mapping.

In nominal measurement different numbers only reflect different units of classification (for example: 0 = single, 1 = married, 2 = widowed, 3 = divorced). Obviously no bigger–smaller interpretation or numerical operation (like addition or subtraction) is permissible in nominal measurement. In ordinal measurement the assessment correctly maps bigger–smaller relationships in behavioural variations (as in ranking data: person A was faster than B, B was faster than C) but not magnitudes of differences between behaviour states. In this case equal intervals in the assessment result cannot be taken to reflect equal-sized differences in state of behaviour. Therefore, ordinal assessment results too must not be subjected to numerical operations like addition or subtraction. In interval measurement assessment results will map correctly bigger–smaller relationships and size of differences in the targeted dimension of behaviour. Many personality and intelligence tests are constructed at the level of interval measurement. In this case numerical operations of addition and subtraction are permissible, while operations involving multiplication or division are not. These operations are only permissible for so-called ratio-scaled measurement, in which the zero point of measurement has been proven identical to the absolute zero point of the underlying dimension of behaviour.

Historically, present day psychometric models and methods are rooted in so-called mental measurement, that is psychological assessment designed to measure inter-individual differences in mental performance (on tests of intelligence, visual memory, spatial orientation, logical reasoning, etc.). The underlying assessment principle is that of behavioural sampling, i.e. of selecting a limited number of items of observation (test items, intelligence problems, perceptual tasks, etc.) in a way that will allow for representative generalization with respect to an hypothesized underlying trait (of general intelligence or memory aptitude). Later this assessment approach has been employed also in the assessment of non-aptitude traits, like personality dimensions or interests, and has been extended further to accommodate not only inter-individual assessment, but also intra-individual tests of state variations, of situation-specific patterns of behaviour or behavioural change as a function of development or as a result of implemented intervention (as in psychotherapy). See Pawlik (2000) for a more detailed coverage of these different modes of psychological assessment.

PSYCHOMETRIC QUALITY STANDARDS

Different psychometric theories of assessment differ in the assumptions (axioms) on which a psychological measurement theory is based. In so-called classical test theory (CTT) one assumes that a person's observed test score is equal to the sum of her/his true score in the underlying trait and an unsystematic error term (error of measurement), which will be linearly uncorrelated

with variations in true test score and with variations in true or error score on any other test (ideal random variable). Then it can be shown that the squared standard deviation (variance) of observed test scores must be a sum of the variance of the true scores (true variance) and the variance of the error terms (error variance). In this theory two tests (1, 2) are called strictly parallel, if the true scores on test 1 and 2 are the same for any one person and if both tests 1 and 2 have same-sized error variance. Then it can be shown, mathematically, that the product-moment correlation of two strictly parallel tests equals the ratio (quotient) of the true score variance to the observed score variance on any one of them. This ratio is called test reliability. It gives the size of the true variance as a percentage of observed test score variance.

Different methods have been developed (parallel test correlation; retest method; split-half reliability; internal consistency measures) for estimating the reliability of an assessment method. According to common standards a reliability of 0.75 to 0.80 is considered minimum requirement for application of that method in practical psychological assessment work. (Reliability of at least 0.75 would indicate that at least 50% of the raw score standard deviation [square root of $0.25 = 0.50$] is unaffected by errors of measurement.)

A second and equally important quality standard of psychological measurement is called validity. It refers to the degree to which a psychological assessment (test or other) measures that and only that psychological variable or attribute it is designed to measure. Criterion validity is a frequently employed variant of test validity. It is given by the correlation between observed test scores and a targeted external criterion (like: final exam scores in an educational curriculum which the test is designed to predict; or for a clinical questionnaire of generalized anxiety: patients' anxiety assessments given by ward staff). Reliability is a necessary but not sufficient prerequisite of validity. It can be shown that the validity of an assessment method cannot exceed the square root of its reliability. Once the criterion validity of a test is known, one can compute the standard error of predicting a person's criterion score on the basis of her/his test scores. While an assessment method has one and only one reliability, it may have different validity for different traits, attributes and criteria.

In research and psychological theory development, often a second kind of validity is given even more preference: the so-called construct validity. In construct validation, the validity of an assessment method is estimated by the degree to which this method will yield empirical results in accord with hypotheses derived from the theory in which the construct is embedded (convergent validity) and, at the same time, not in accord with hypotheses linked to an unrelated construct (discriminant validity). For example, one would expect that scores on a test of general anxiety will be lower after psychotherapeutic treatment known to reduce general anxiety, yet remain unaffected by placebo treatment. In this case construct validity refers to the degree to which these theory-based predictions can be shown to hold for the test in question.

Next to reliability and validity, several additional psychometric quality standards of assessment have been introduced. These include:

- objectivity of administration of an assessment method: the degree to which situational context variables of an assessment, the behaviour of the tester and other circumstantial factors are standardized and proven, not to give rise to differences in assessment results;
- scoring objectivity: the degree to which different scorers of the same assessment protocol will yield identical scoring results;
- the nature of statistical norms (population reference statistics for test interpretation): size and representativeness of the standardization population, proper choice of standardized score;
- discriminative power of an assessment method: the degree to which true differences in state of behaviour will be assessed by the method, be it in inter-individual comparisons (trait measurement) or intra-individual comparisons (state measurement);
- internal consistency: the degree to which the components (sub-tests, items, scales) of an assessment method measure equivalent psychological entities and can thus be interpreted in a summative way (for example, in a total score or intelligence quotient);
- response objectivity: the degree to which assessment results can be influenced by the

testee, be it voluntarily (faking good or faking bad) or involuntarily;
- level of test fairness: the degree to which the test content, the sampling of test items, the scoring procedure and the rules for test interpretation are equally representative and valid for testees from different sub-groups of a population (male vs. female, young vs. older adults, different ethnic origin, etc.).

In most countries these psychometric standards of assessment are complemented by additional ethical/legal standards of psychological testing, especially with reference to the protection of privacy, the principle of informed consent, and, particularly important, the principle of confidentiality.

DEVELOPMENT OF PSYCHOMETRIC ASSESSMENT METHODS

Next to assessment quality control, psychometric theories provide a basis also for standards in development of assessment methods. In order to optimize test construction with respect to the fore-mentioned pychometric quality criteria of psychodiagnostic assessment, the literature on psychometric test construction comprises ready-to-implement methods for:

- adequate definition of target traits or states or criterion measures;
- choice and sampling of units of observation (items) in test construction;
- methods of item analysis for assuring sufficient internal consistency, for developing parallel tests and alternate forms of an assessment instrument;
- procedures to be followed in test standardization;
- alternative procedures to be followed in assessing the above mentioned quality standards.

When choosing among alternative assessment methods for a given assessment problem, the psychologist is trained and professionally committed to carefully examine available information on the standards followed in test development and on psychometric quality control (especially with respect to reliability and validity) of assessment results obtained with the method in question. In many countries the national code of ethics for psychologists make it compulsory for a psychologist to carefully examine the psychometric appropriateness of an assessment method (with respect to standards of test development and test quality control) before applying it in practical service.

PSYCHOMETRIC ASSESSMENT THEORIES

CCT is still the most widely employed psychometric theory for psychological assessment, despite certain inherent methodological shortcomings. To combat these, more advanced mathematical–statistical models have been developed which employ detailed (and empirically testable!) assumptions about the statistical relationship between observed test scores and underlying true scores. In such a model one specifies a probability function relating observed item scores to underlying true trait scores. (This item-characteristic function can be chosen, for example, to follow the integral [ogive function] of a normal density function or a logistic function.) The reader is referred to the classical text by Lord and Novick (1968) for an introduction into probabilistic psychometric theories. Probabilistic psychometric measurement yields estimates of persons' true scores, of test item difficulties, and of test reliabilities that are statistically independent of specifics of the sample of persons and items under study. Furthermore, these more advanced psychometric theories are suitable for so-called adaptive testing (tailored testing). In such an assessment, those and only those items (questions, test problems, questionnaire statements, etc.) are administered whose item difficulties range close to a person's estimated attribute score. In this way psychological assessment can be designed more economically (in testees' and testers' time and effort) and, at the same time, optimally reliable within pre-set standards of reliability. Adaptive assessment designs lend themselves most readily to computer-assisted testing, which has come to replace older paper–pencil tests in a growing number of assessment situations.

The reader may consult these texts, handbooks and handbook chapters for a more detailed introduction into the psychometric theory of

psychological assessment: Anastasi (1988), American Psychological Association (1985), Lord and Novick (1968), Pawlik (2000), Wainer (1990).

FUTURE PERSPECTIVES AND CONCLUSIONS

The development of psychometric theory has established a firm and professionally obligatory basis for the development of psychodiagnostic assessment instruments and their quality evaluation with respect to objective standards of reliability and (prognostic or diagnostic) validity. More recent developments in probabilistic item-response theory have extended this basis to provide an advanced basis for the measurement of psychological change and for testing procedures designed to assess a person's trait values with the smallest-possible number of items thereby fulfilling a pre-selected level of psychometric accuracy (reliability). In all likelihood, future developments of psychometric assessment will develop further today's technologies of computer-assisted testing and of ambulatory assessment of behaviour traits under everyday life conditions, outside the (physical and methodological) refinements of a laboratory or stationary testing situation. If implemented successfully, these ambulatory techniques of psychological assessment will expand presently available methods for studying behaviour changes in multiple-base line designs (as frequently needed in clinical testing), of studying intra-individual variation due to changes in mood state, activation level or co-variant environment conditions, and provide for more advanced methods of intervention-related assessment in educational and clinical psychology.

THEORETICAL PERSPECTIVE: SYSTEMIC

INTRODUCTION

Historical Roots

Depending on viewpoints, different developmental pathways of the systemic approach can be identified such as (i) family therapy schools, (ii) solution focused and resource oriented concepts of clinical practice, and (iii) the dynamic systems approach in complexity science. The first two grew up on the soil of psychotherapy practice whereas the third belongs to the field of formal and empirical sciences. Family therapy as well as solution-focused approaches intend to stimulate changes of individual or interpersonal patterns (patterns of feeling, thinking, behaving, and of social communication). In order to do this, they need an idea of how complex systems create and transform such patterns. In the last

two decades, the theories and methodologies of complex dynamic systems were used to get such ideas. Surrounding the concept of self-organization, theories and assessment tools provided the basis for empirical research on psychotherapy change processes.

Basic Assumptions

The systemic approach focuses on dynamics, interconnectedness, and complexity of psychological, physiological, and social phenomena. Its look at the world adopts the perspective of time, development, and pattern transitions. This look is qualified by its structure of knowledge and its methodological approaches, not by the 'objects' or the phenomena under consideration (e.g. families). This perspective refers to interpersonal constellations such as couples, families, or social groups in so far as features like dynamics and complexity are at the core of diagnostic interest. The mere classification of social units into categorical or dimensional systems does not fulfil any criteria of systemic assessment procedures. The feeling, thinking, and behaving of individuals is also at the core of interest, as well as (individual or coupled) brain dynamics.

Qualities of social systems like interactional styles, dyadic coping, expressed emotions, cohesiveness and many others are of interest, if they can be seen as a result of dynamic processes. In terms of self-organization theory these qualities are collective order parameters of a social system, reducing the degrees of freedom of behaviours and cognitions of the system members (subsystems or components). Components become part of coherent patterns which are determining their behaviour (top-down causality), but the other way round, interactions between components constitute emergent patterns and qualities not yet existing at the level of components (bottom-up causality). Global qualities can also act as constraints and/or boundary conditions of the realized system dynamics – more or less in touch with these dynamics and so themselves more or less prone to change.

If individual or socially shared cognitions can be seen as self-organized products of such circular causalities between micro- and macro-level dynamics, social as well as individual constructivism finds its theoretical foundation in the systemic processes of self-organization. Spontaneous order formation in brains, minds, and societies is the basis of meaningful constructions or 'Gestalts', and this is the reason why constructivist and systemic procedures of assessment share quite similar epistemological backgrounds.

ASSESSMENT PROCEDURES

Systemic assessment techniques can be classified along the axes of (i) static or dynamic portraying, (ii) qualitative or quantitative methods, and (iii) practical or research oriented purposes.

Visual Representations of Interpersonal Constellations

Well-known visualization tools like family genograms, sociomatrices based on preference choices between group members, structural models of relationship qualities or group and family sculptures (incorporated by real individuals or realized by symbols like coins or Szeno Test figurines, as in the method of family boards) are widely used in systemic therapy (*cf.* Cierpka, 1996; Schiepek, 1991, 1999). Following our taxonomy, these procedures usually are realized for practical purposes and will be found at the static and qualitative end of the axes. They are systemic only in as far as they try to portray the complexity of interpersonal constellations, but in a first step, any information of dynamic qualities is missing. In a second step, however, they help to initiate communicative and emotional dynamics within the portrayed social system, and – applied repeatedly and entering by this an iterative cycle between representation and action – they play an important role in supporting therapeutic change processes.

Circular Questions

A classic example for a change instigating assessment procedure is circular questioning. The interviewer is not interested in 'facts as they are', but in facts related to other facts, in shapes (Gestalts) on their backgrounds, in information related to the information producing systems, in observations related to their observer(s), in the present mirrored by the future, in distinctions producing distinctions. The exchange of

perspectives on interaction patterns and pattern descriptions within groups is a transformation-inducing process.

Subjective Reconstruction of a System's Evolutionary Pathways

In contrast to the iterative portraying realized by circular interviewing procedures there are other methods focusing on system dynamics in a more direct way. One of these is the graphic representation of the developmental patterns of certain important system qualities. These developmental patterns will be graphically represented using a system of coordinates (with the *x*-axis representing the time span of the development under observation [hours, days, months, or years] and the *y*-axis representing the intensity of the qualities). The resulting retrospective time series characterize the subjective view on developmental processes of an individual or a group (team, couple, or family). Notions of relevant life events, phase specific resources, realized decisions, and extrapolations into the future can enrich the dynamic patterns.

Idiographic Systems Modelling

Going beyond this finger exercise in dynamic thinking one can develop hypotheses about the interactions and feedback-loops between relevant systems variables, which can be graphically represented by a network diagram (idiographic systems model). Like a complex macromolecule composed of smaller molecules, one gets a macro-hypothesis built up of smaller partial hypotheses. All these assumptions represent different aspects or components interwoven into a complex bio-psycho-social process, which generates the characteristic dynamic patterns of the system. In clinical practice, these models represent some kind of functional analysis of problem behaviour or abnormal bio-psycho-social patterns. They integrate a broad basis of knowledge and combine some case-relevant parts of this knowledge into multi-perspective views on clinical problems. The specific gain of this procedure beyond a mere addition of hypotheses and information is the consideration of feedback-loops between the system components (variables). Following the paths interrelating the components, one gets some idea of the characteristic evolutionary patterns of the phenomena under consideration. Despite using theoretical (nomothetic) and empirical results from psychology and other fields, the aim is a specific idiographic understanding of single cases. Additionally, qualitative network models help for an understanding of system functioning and can, therefore, be used in order to prepare further steps into formalized models.

Computer Simulations

Consequently, systemic assessment strategies end in simulation procedures, i.e. in the transition from qualitative to formal modelling. Different formalization approaches are available in the field of system dynamics. Widely used are difference equation systems, differential equations, cellular automata, autonomous agents, neuronal networks, and hybrid (mixed) approaches (*cf.* Schiepek, 1999). Computer simulations open the door to a deeper understanding of dynamic complexity. Most of the phenomena psychiatry and clinical psychology are dealing with can be understood as 'dynamical diseases' characterized by specific dynamic structures and by different degrees of stability or instability. Their generating mechanisms are nonlinear mixed feedback systems that combine increasing, i.e. exciting, and decreasing, i.e. damping, processes.

Gaming Simulations

In the repertory of systemic assessment, not only computer simulations but also real life simulations or gaming simulations are widely used. This enlarged role-playing starts from carefully prepared social constellations and problems. The evolution of dynamic scenarios and problem solutions will take place in a self-organized manner. Real life simulations are realized in order to better understand complex social systems, to anticipate possible problems and developmental pathways before entering real changes in organizations, or to do research on social systems.

Real-Time Monitoring of Change Processes

If there exist some possibilities to measure the relevant system variables in a prospective manner (by daily ratings or repeated observations, for example), one gets the material for time series

analysis. Before entering more sophisticated analysis procedures, a mere visual inspection of time series data can result in surprising insights – but sometimes in misleading interpretations, too. Statistical tools are being developed for practical applications. In practice, clients' diaries, therapy session feedback sheets, or other documentation instruments can be of great importance.

Video Based Coding Systems

Especially within psychotherapy research, video based coding systems are used to get time series data of dynamic processes. An observation system of the therapist's behaviour is the *Rating Inventory of Solution Focused Interventions* (time sampling: one minute). Another method develops its own observation categories by an idiographic strategy. This method, called *Sequential Plan Analysis*, allows for a highly resolved, video based encoding of the self-presentation behaviours of interacting persons (time sampling: 10 seconds). The synchronicity of different behaviour aspects (so called 'interactional plans') of the interacting persons results in dynamic patterns, which can be visualized by an encoding system very similar to musical scores. Every instrument of the orchestra (every plan) only realizes one single note which can be played or not, but out of the synchronicity of these on–off-sequences melodies, rhythms, and harmonies are emerging. By means of intensity ratings of the concrete behaviours representing interactional plans at the concrete level, the time dependent evolution of the plans can be quantified. The resulting time series can be analysed by linear and non-linear methods (Kowalik et al., 1997; Schiepek et al., 1997).

Configuration Analysis

Horowitz (1987) identifies sequential patterns of 'states of mind'. These are global qualities of psychological functioning and of constituting social relationships. 'States of mind' integrate actualized beliefs, situation perceptions, emotions, coping reactions, and images of the 'self' and the 'other'. By this, states can be seen as order parameters or attractors of the 'stream of consciousness', and a sequence of states represents order-to-order transitions of psychosocial system dynamics.

Scientific as well as practical interests of systemic assessment and analysis methods focus on the identification of dynamic order (attractor types), order transitions, and the degree of stability or instability of dynamic processes. As living systems are engaged in learning, adaptation, and evolutionary processes, they realize dynamic changes. Their behaviour is not only characterized by non-linear dynamics, but also by nonstationary ones. Consequently, existing analysis methods for non-stationary time series get increasing importance (Vandenhouten, 1998).

EVALUATION CRITERIA

The quality criteria of dynamic assessment are partially different from static assessment. Instead of 'true values' the aim is to identify 'true dynamics', i.e. to distinguish these from measurement biases and dynamics caused by noise or error. The discussion of criteria in systemic assessment establishes different priorities, depending on purposes or contexts (more practical or more scientific), and reflects the epistemological conditions of the observing (assessing) system as well as the relationship between observing and observed (assessed) systems (*cf.* Schiepek, 1991, 1999).

Most assessment methods used in systemic practice realize assessment as well as change inducing functions at the same time. System representations produced by the system itself or mirrored from the outside are frequently instigating reactions or transformation processes. This reactivity is intended, so that assessment procedures involving clients in practice have to be judged not only by criteria of reliability and validity, but also of effectiveness and usefulness in terms of clients' goals.

FUTURE PERSPECTIVES AND CONCLUSIONS

The systemic approach in its formal and methodological aspects is not restricted to certain types of interpersonal constellations (like couples or families) or to clinical applications. One important field of applications will be the understanding and assessment of management processes as well as transformations of profit and non-profit organizations. An important role is played by the computer-assisted real-time monitoring of change processes (including

human as well as monetary and structural aspects) and the possibilities of real-time data analysis, whose results will be fed back to management and decision processes. Qualities like the stability or instability of the ongoing process are of important relevance for such decisions. In the economic field, gaming simulations will become part of assessment centres, depending on the accepted insight that competencies in complexity management and systemic thinking are qualities of successful leaders.

Another field of application is the real-time assessment of psychotherapy processes providing both therapists and clients with relevant information about ongoing dynamics. If it is true that the human brain is one of the most prominent, complex, non-linear, self-referential, and self-organizing systems, the analysis of signals from the brain will remain an important field of non-linear portraying and analysis methods. In psychological research, using systemic assessment tools stands for the transition from static to dynamic thinking.

THINKING DISORDERS ASSESSMENT

INTRODUCTION

Regardless of the instruments used, the clinical assessment of thought disorder must begin with clarification of the meaning of this illusive concept. 'Thought disorder' is a widely used and often misunderstood term with a history of confusion regarding the definition, underlying mechanisms, and diagnostic specificity. Following a presentation of a working definition of disordered thinking and a brief mention of various areas of conceptual confusion, I summarize categories of assessment instruments used to measure thinking disturbances.

DEFINING THOUGHT DISORDER

A comprehensive definition of thought disorder encompasses a broad perspective that includes not only traditional concepts such as impaired pace and flow of associations, but also such factors as

inefficient focusing and attentional processes; deviant word usage; errors in syntax and syllogistic reasoning; inappropriate levels of abstracting; failure to maintain conceptual boundaries; and a breakdown in the discrimination of internal perceptions from external ones. Such a definition captures the multidimensional nature of disturbances in thought organization (Kleiger, 1999).

CONTROVERSIES, PROBLEMS, AND CHALLENGES

Measuring disordered thinking is beset with a number of controversies, potential problems, and challenges. Making inferences about an intangible variable such as thinking from overt speech is controversial and has led some to question the validity of the construct of 'thought disorder'. Because the construct itself is called into question, instruments which purport to measure disordered thinking, instead of disordered speech, for example, are vulnerable to the criticism that they lack sufficient construct validity to justify claims of their effectiveness as diagnostic tools.

Another difficulty that plagues assessment effort is the lack of universal agreement over what constitutes disordered thought. There is general agreement that disordered thinking occurs in a variety of conditions, falls along a continuum of severity, and reflects a number of different anomalies in thinking. However, there is no absolute standard for classifying these anomalies of thought. Furthermore, different researchers often employ different techniques to assess different types of disturbed thinking. Although there may be overlap in many of the variables studied by different assessment methods, comparison between the various techniques is often difficult. Different assessment approaches may employ different names for similar variables or use the same name for essentially different types of disordered thinking.

Achieving sufficiently high inter-rater reliability or clinical sensitivity with the instruments is a challenge since many of the ratings or scoring systems themselves can be quiet intricate, difficult to learn, and subject to interpretation. Research on the most prominent scales and scoring systems demonstrates that significantly high inter-rater reliability is possible; however, learning some of these rating systems usually requires more than familiarizing oneself with the manuals. Often consultation with the researchers, who pioneered the ratings scales or scoring systems, is necessary in order to use the instruments competently.

The impact of phase of illness, medication, and context must be taken into consideration when assessing disordered thinking. The degree to which an individual's thinking is disorganized will depend on whether she/he is in an acute phase, or in a partial or complete remission. Valid measurement of disordered thinking also requires one to evaluate the subject's motivation, attitude, the context in which the idiosyncratic thinking is revealed. Is the subject aware of the bizarreness of his or her speech or ideas and, if so, what is their attitude toward it? Is idiosyncratic speech used to shock, control, or entertain? The presence of unusual ideas or odd speech does not constitute immediate grounds for inferring the incursion of a psychotic process.

ASSESSMENT INSTRUMENTS

Disordered thinking can be assessed by a variety of instruments ranging from formal psychological tests to structured interview techniques. Chapman and Chapman (1973) reviewed five methods for measuring thinking disturbances in schizophrenia. Included among these were (1) clinical descriptions of spontaneous verbalizations, (2) clinical interpretation of verbalizations made to standardized stimuli, (3) classification of verbalizations into predetermined categories, (4) standardized tests with formal scoring of deviant verbalizations, and (5) multiple-choice techniques. These methods differ in the degree to which examiners/interviewers (1) specify the stimulus situation, (2) restrict the number of possible responses an individual can give, and (3) limit the scoring categories for these responses. Simplifying matters, Koistinen (1995) divided assessment techniques into two broad categories, those using structured interview techniques and those based on psychological tests.

Interviews with Rating Scales

One of the most popular interview-based rating scales is Andreasen's Scale for the Assessment of Thought, Language, and Communication (TLC)

(Andreasen, 1978). This scale consists of definitions and directions for rating the severity of 20 forms of thought disorder manifestations along either a 4 or 5 scale. Subjects are given a standard interview of approximately 45 minutes. Beginning with an unstructured sample of the subject's speech, the interviewer then asks a series of specific questions regarding topics such as family life, politics, and religion. The interrater reliabilities of each of the subtypes defined by Andreasen have been shown to be sufficiently high to make the TLC Scale a useful instrument for research and clinical assessment of disordered thought, language, and communication. As a tool to aid in differential diagnosis, Andreasen demonstrated both quantitative and qualitative differences in TLC scores between different groups of psychotic patients.

Psychological Tests

Tests such as the MMPI/MMPI-2 and MCMI offer the advantages of time-efficiency and ease of administration; however, they provide, at best, crude measures of deviant thinking. More recently Butcher (Butcher et al., 1989) developed MMPI-2 Content Scales, which included a Bizarre Mentation scale. This special scale like Wiggin's older Psychoticism scale (Wiggins, 1966) was designed to measure patients' reports of strange thoughts and psychotic experiences.

A variety of other brief or self-administered paper and pencil tests, such as the Rust Inventory of Schizotypal Cognitions (Rust, 1987), the Schizotypal Personality Questionnaire (Raine, 1991), the Whitaker Index of Schizophrenic Thinking (Whitaker, 1973), were all developed to assess vulnerability to schizophrenia-spectrum thought disorders.

Self-report inventories are a good place to begin but they cannot provide a detailed assessment of the nature of disturbed thought processes. Even attempting to identify the presence of psychosis with these instruments is usually accompanied by unacceptably high false positives and negatives. True and false or multiple-choice questions, if read carefully, understood correctly, and answered truthfully, might be sensitive to some unusual ideas and experiences; however, without a sample of verbal behaviour and an opportunity to inquire into idiosyncratic responses, it is difficult to judge anything about the severity or quality of subtypes of disordered thinking.

Since the Rorschach was developed more than 70 years ago (Rorschach, 1921), researchers and clinicians have devoted enormous attention to identifying signs of schizophrenia and other forms of serious psychopathology. Although early Rorschach studies mirrored general psychiatric diagnostic trends, which assumed an isomorphic relationship between schizophrenia and disordered thinking, sophisticated ways of conceptualizing and measuring through pathology with the Rorschach have been developed. Virtually all Rorschach systems for assessing disordered thinking are based on the work of Rapaport (Rapaport et al., 1968), who made thought disorder scoring a key aspect of the test.

There are two contemporary Rorschach approaches for scoring thought disorder manifestations. The Special Scores of the Comprehensive Rorschach System (Exner, 1993) and the Thought Disorder Index or TDI (Johnston & Holzman, 1979) both assess a range of deviant thought and speech elements embedded in verbalizations and reasoning used to justify a Rorschach response. Both instruments were developed in the mid-1970s but had relatively separate developments over the last several decades. Exner's Comprehensive System is the most commonly used approach for administering, scoring, and interpreting the Rorschach, while the TDI was developed as a research instrument and, as such, has made few inroads into clinical assessment practice. The TDI is made up of 23 different forms of thought disorder, scored at 4 levels of severity (0.25, 0.50, 0.75, and 1.0). A more complex instrument to learn, the TDI is useful for identifying subtle differences among different groups of psychotic subjects, aiding in differential diagnosis of psychotic disorders. Interrater reliability is relatively good for ratings across different severity levels, with interclass correlations ranging from 0.72 to 0.77 (Coleman et al., 1993). Apart from it being a difficult instrument to learn, one drawback of the TDI is that it was developed using the Rapaport Method of Rorschach administration, which differs from the standards used by the more popular Comprehensive System. Nonetheless, the TDI is viewed not only as a robust measure of thought disorder, but also sensitive to identifying differential diagnostic patterns among different groups of psychotic subjects.

By contrast, the Special Scores of the Comprehensive System offer a much crisper and more economical approach to identifying major thought disorder categories. Four major categories comprising eight different scores can be scored according to level of severity (Level 1, mild slippage; Level 2, moderate and severe). By reducing the number of categories, the Comprehensive System ensures better inter-scorer reliability and ease of learning. Different scores are weighted according to their level of severity and entered into a summary index used to help make the diagnosis of Schizophrenia (SCZI). However, the SCZI is inadequate as a specific diagnostic indicator, yielding many false positives as many non-schizophrenic subjects, with other forms of psychoses, trauma, or personality disorders, often score positively on this index. The SCZI is probably better conceived of as an index of psychotic thought, as opposed to an index sensitive to one particular diagnostic syndrome.

FUTURE PERSPECTIVES

Traditionally studied as a psychological construct, researchers have increasingly sought to understand disordered thinking from a cognitive neuroscience perspective. Cognitive deficits in working memory, executive functions, and information processing have been found to be present in individuals suffering from schizophrenia-spectrum illnesses. Cutting edge research is being conducted to examine the correlation between thought disorder, neuropsychological measures, and neuroanatomical brain. Increasingly, we can expect neuropsychological studies of thought disturbances in affective, trauma-based, characterological, and anxiety-related disorders.

CONCLUSIONS

Thought disorder has been shown to be a construct that is reliably and validly assessed by a range of instruments. Researchers generally favour more rigorous methods that employ interview and rating scales such as the TLC or Rorschach approaches such as the TDI. Clinicians can use a variety of personality inventories and self-report forms to screen for the presence of thought disorder and the Comprehensive Rorschach System which offers a user-friendly and scientifically sound method of measuring different forms of disordered thought.

TIME ORIENTATION

INTRODUCTION

Time perspective (TP) is the often non-conscious process whereby the continual flow of personal and social experiences are parcelled into temporal categories, or time frames, that help to give order, coherence, and meaning to those life events. These cognitive frames may reflect cyclical, repetitive temporal patterns or unique, non-recurring linear events in our lives. They are used in encoding, storing, and recalling experienced events, as well as in forming expectations, goals, contingencies, and imaginative scenarios. Between the abstract, psychological constructions of prior past and anticipated future events lies the concrete, empirically centred representation of the present action moment.

When a tendency develops to habitually overemphasize past, future, or present temporal frames when making decisions, it serves as a cognitive temporal 'bias' toward being past, future, or present-oriented. When chronically elicited, this bias becomes a dispositional style, or individual difference variable, that is characteristic and predictive of how the individual will respond across a host of daily life choice situations. Of course, there are variations in the degree to which a person utilizes these temporal orientations, and there may be situations in which each of these orientations will lead to an optimal decision. Temporal bias may include either habitual over or under use of one or more of these temporal frames. Such limiting biases are in contrast with a 'balanced time orientation', an idealized mental framework that allows individuals to flexibly switch temporal frames between past, future, and present depending on situational demands, resource assessments, or personal and social appraisals.

PREVIOUS RESEARCH ON TIME PERSPECTIVE

One possible reason why this intriguing, seemingly central aspect of the human experience – time – has not been incorporated into the current domain of psychological science may be due to the disjointed, non-cumulative nature of past research, the lack of adequate theory, and the absence of a standard, reliable, and valid measure for assessing TP. Given the complexity of this construct, it is no wonder that time perspective has been measured and operationally defined in a variety of different ways by independent investigators. Most research has tried to relate either future or present orientations to other psychological constructs and to their effects on selected outcome behaviours, with relatively little attention to past orientations. In general, future orientation has been shown to be related to many positive consequences for the individual in Western society, such as higher SES, superior academic achievement, less sensation seeking, and fewer health-risk behaviours. The opposite holds for those with a dominant present-orientation, who are seen as at risk for many negative life consequences, among them mental health problems, juvenile delinquency, crime, and addictions, when they function in a predominant future-oriented society (see, for example, DeVolder & Lens, 1982; Fraisse, 1963; Levine, 1997; Nuttin, 1985; Strathman, Gleicher, Boninger & Edwards, 1994; Zaleski, 1994).

Previous attempts to capture the complexity of TP in a single index have used: Thematic Apperception Test; Experiential Inventory (Cottle, 1968); Circles Test (Cottle, 1976); Motivational Induction Method (Nuttin, 1985); questionnaires (Bond & Feather, 1988); and Time Lines (Rappaport, 1990), among others. However, none of these methods has been widely accepted because of their low reliability or scoring difficulties. Because the meaning of TP must be closely linked to the standardized operations used to assess it effectively, such disparate definitions and methods have hindered the fuller development of this domain of psychological inquiry.

Attempts at conceptual simplification have tended to focus on only a single dimension, such as the present or future, without the

complicating influence of the other temporal dimensions, such as a future anxiety scale (Zaleski, 1996), or the Consideration of Future Consequences (CFC) scale (Strathman et al., 1994), and a well-known sensation-seeking scale whose features emphasize present-oriented functioning (Zuckerman, 1994). While these scales are improvements over previous graphical or story-based attempts to measure TP, they are literally one-dimensional. By focusing on but one dimension, they fail to provide assessments of the relative strengths of the other dimensions within individual temporal profiles. Moreover, they assume, incorrectly, that scoring low on a scale of future orientation is equivalent to being highly present-oriented, or scoring low on a measure of the present is equivalent to being future-oriented. Notably absent from these scales is any representation of the past.

A single pencil-and-paper scale – the Zimbardo Time Perspective Inventory (ZTPI) – can be productively used to illustrate the development of a valid assessment instrument and to introduce psychological constructs with which time perspective may be related (Zimbardo & Boyd, 1999). The ZTPI is easy to administer and score, with a clear, replicable factor structure, reasonable subscale reliabilities, and demonstrated validity. It provides a quantifiable measure of multiple time frames as individual temporal profiles, assesses broad dimensions of time perspective, and is built on a theoretical foundation that combines motivational, emotional, cognitive, and social processes that are assumed to contribute to, and are in turn influenced by, the operation of time perspective. At a conceptual level, TP may unite or integrate diverse constructs in previously unrecognized ways, and hopefully utilization of the ZTPI will serve as an impetus to bring order, coherence, and predictive power to the next generation of research on TP.

CONSTRUCTION OF A SAMPLE SCALE

Overview

A first empirical demonstration of the utility of a scale to measure such differences came from a convenience sample of more than 12,000 respondents to a *Psychology Today* magazine questionnaire that was prepared based on exploratory investigations (Zimbardo & Gonzalez, 1984; Gonzalez & Zimbardo, 1985). Refinement of the ZTPI was empirically driven, based on repeated factor analyses of the pool of statements thought to characterize different time perspectives. When factor analysed, these items, collected from many different sources, reliably produced five distinct factors. There was no a priori theoretical prediction of the number or characteristics of the factors that we would obtain; their nature was determined solely by the pool of characteristic statements and repeated factor analyses of this pool. After establishing the stability of the five-factor structure, individual items were analysed and revised in order to maximize factor loadings and increase the internal consistency of the subscales. The final factor analysis described below thus represents the end product of more than a decade long multipronged approach to the development of the ZTPI.

Exploratory Factor Analysis

The ZTPI asks respondents to indicate how characteristic a statement is of them on a 5-point Likert scale, where one endpoint is 'very characteristic' and the other is 'very uncharacteristic'. Exploratory principal-components factor analysis (using varimax rotation and replacement of missing values with the mean; $N = 606$) revealed five distinct Time Perspective factors, which explained 36% of total variance. The five latent constructs identified were theoretically viable and were similar to those obtained in our earlier analyses.

The Five ZTPI Factors

Past-Negative

The first factor of the ZTPI reflects a generally negative, aversive view of the past, labelled the 'Past-Negative'. Items that comprise this factor include, 'I think about the bad things that have happened to me in the past', 'I think about the good things that I have missed out on in my life', and 'I often think of what I should have done differently in my life'. Because of the reconstructive nature of the past, these negative attitudes may be due to actual experiences of unpleasant or traumatic events, to negative reconstruction of benign events, or a mix of both. However, it

seems reasonable to assume that the surprising prominence of this first strong factor is greater in our current United States cultural context in which the false memory syndrome/repressed memory controversy is publicized prominently and where PTSD is reported frequently in the media.

Present-Hedonistic

The second factor reflects a hedonistic, risk-taking, 'devil may care' attitude toward time and life. It includes such diverse items as, 'Taking risks keeps my life from becoming boring', 'I do things impulsively', 'I often follow my heart more than my head', and 'When listening to my favourite music, I often lose all track of time'. It suggests an orientation toward present pleasure with little concern for future consequences.

Future

The third factor reflects a general future orientation. Items typical of the Future factor include, 'I am able to resist temptations when I know that there is work to be done', 'It upsets me to be late for appointments', 'I complete projects on time by making steady progress', and negatively, 'I take each day as it is rather than try to plan it out'. The Future scale suggests that behaviour is dominated by a striving for future goals and rewards.

Past-Positive

The fourth factor reflects an attitude toward the past that is very different than that captured by the first factor. While the first factor suggests trauma, pain, and regret, the Past-Positive reflects a warm, sentimental attitude toward the past. Items that load on the Past-Positive factor include, 'It gives me pleasure to think about my past', 'I get nostalgic about my childhood', 'I enjoy stories about how things used to be in the "good old times", and 'I like family rituals and traditions that are regularly repeated'.

Present-Fatalistic

The fifth and final factor of the ZTPI reveals a fatalistic, helpless, and hopeless attitude toward the future and life. Items that comprise the Present-Fatalistic TP factor include, 'My life path is controlled by forces I cannot influence', 'You can't really plan for the future because things change so much', and 'Often luck pays off better than hard work'.

CONVERGENT AND DISCRIMINATE VALIDITY

Having established the factor structure, test–retest reliability, and internal consistency of the ZTPI, we turn to issues of validity. As with the basic scale construction process, validation was complicated by the nature of this ephemeral but pervasive phenomenon. Time permeates and defines our existence, so much so that it can be related to many diverse psychological constructs. Any attempt at validation, therefore, must include numerous psychological measures that conceptually might be related to any of our five TP factors. We next demonstrated the relationships of each of our scale factors with a network of traditional measures assumed to share some common variance with them. Our analyses revealed the unique contribution of our five temporal factors within the correlational structure existing between them and a dozen traditional measures. Space considerations do not allow us to detail all of the hypotheses we considered. Please see Tables 1 and 2 for a summary of the relationship between factors of the ZTPI and other well-established psychological constructs, and Zimbardo and Boyd (1999) for a fuller presentation of our validation studies.

FUTURE PERSPECTIVES AND CONCLUSIONS

As the pace of life in our post-modern world continues to accelerate, the role that time plays in the course of our lives is likely to become more salient and, perhaps, more divisive. Individuals may become blindly devoted to the pursuit of the future, others may become engrossed in the emotion of the present, and others may retreat to the comfort – or terror – of the past. The fortunate will balance the temporal demands of life with equanimity. Of how time will change in the future and of how individuals will choose to spend it, we cannot be certain. We can be certain,

***$p < 0.001$; **$p < 0.01$; *$p < 0.05$

however, that time will play an increasing role in our lives, and it will be imperative that scientists have valid assessment instruments with which to measure it. We hope that other researchers will agree that time perspective is a psychological concept whose time has come.

TOTAL QUALITY MANAGEMENT

INTRODUCTION

This entry is intended to describe in general terms Total Quality Management, discuss some international movements to implement TQM, and focus on the European Foundation for Quality Management (EFQM) Model of Excellence as a practical tool for implementation through the assessment of performance of a psychological organization. All of these models sponsor different yearly Prizes and Awards on Excellence or Total Quality Management.

In order to introduce the reader gradually into the field, we shall cover, in sequence, the basis of Total Quality Management, the content of some of the international models focusing on the EFQM, a summary of the content of the model (criteria and attributes), aspects on self-assessment and performance improvement, and our views and perspectives for the future.

ESSENTIAL IDEAS BEHIND TOTAL QUALITY MANAGEMENT

Total Quality Management deals with managing with quality all functions of the organization. Managing with quality means meeting stakeholders' needs (with emphasis in the customer) through self-assessment, continuously improving efficiency and effectiveness.

Consequently, we could define TQM as a management strategy, based on self-assessment, focused in the customer, continuously improving all activities of all functions through the integration of the employees, and the personal assumption and evaluation of their responsibilities.

From the early artisan times, quality has evolved to Total Quality in the 1980s, but it followed a long journey (Teboul, J., 1991):

- 1930 Statistical control
- 1940 Acceptance plans
- 1950 Reliability and quality control
- 1960 Cost of quality, prevention
- 1960 to 1970 Involvement of everyone (Deming, E.W., 1982), problem analysis (Juran, J.M., 1989) and zero defects (Crosby, P.B., 1979)
- 1980 TQM starts

Let us examine a series of principles which provide the basic philosophy of Total Quality Management. Later in this entry, you will have

the opportunity to observe how these principles are structured in the EFQM Model.

Continuous Improvement Based on Self-Assessment for Learning and Innovating

The basic principle is that every activity is subject to improvement, and to be able to do that it is necessary to learn and apply this knowledge to innovate. This process has to be implemented through self-assessment.

The useful cycle used in science and industry applies: first you observe the results of any specific experience; second you reflect on these results; third you check or verify if your initial assumptions were met and, as a consequence, you learn; finally you take action either to correct towards the direction you want to take or you change your objective.

People Involvement and Implication

The improvement is not possible without the active participation of the people involved, who self-assess and assess the organization. Certainly, implication of management at all levels is needed, but the key to success is the involvement of the employees in the organization.

To do that, people training and development is a basic requirement; but empowerment by delegating authority and recognizing people when they contribute to improvement are ways to achieve employee implication.

Leadership

Leadership, which is 'an attempt at influencing the activities of followers to *willingly* cooperate through the communication process toward the attainment of some goal or goals' (Fleishman & Hunt, 1973: 3), is a complementary requirement to the above. It should be understood at all levels in the organization, even at the personal level: the identification of everyone with the concept that improvement will not be achieved without his or her participation.

Leaders should be able to transmit with clarity the direction they want for the organization. They should as well set the example.

Management by Facts and Data through Evaluation

The results of any process should be evaluated and measured to be able to compare and facilitate the improvement. It is very typical that we, as human beings, compare results in a subjective manner: 'it is *better* than yesterday', 'there has been a *tremendous* improvement', and so on.

Everything *should* be assessed and *can be* assessed, even data related to personal perceptions. One of the attributes of all the results in the EFQM Model is the internal comparison and comparisons with others along the time. No results can be compared without reliable data.

Partnership Development

Suppliers and other related partners should be treated within a significant association environment. Only in this way the organization will work more effectively, with mutual beneficial relationships, built on trust, sharing of knowledge and integration.

Social Responsibility

'The long-term interest of the organization and its people are best served by adopting an ethical approach and exceeding the expectations and regulations of the community at large' (EFQM, 1999: 7).

Customer Focus

The customers, defined as the people who benefit from the product and services of the organization, are the final arbiter of quality. Depending upon their views, loyalty will be lost or assured.

Nemeroff, of Citybank, finds three principal themes in an effective service orientation to customers: '(1) intensive, active involvement on the part of senior management; (2) a remarkable people orientation; and (3) a high intensity of measurement and feedback' (Peters & Waterman, 1982: 165).

To be able to satisfy the *customer*, the organization should focus on customer requirements: the needs of current and potential customers. Actually, the complement should be the clear understanding of the *relevant* indicators

of the customer to be able to *measure* the performance through them.

INTERNATIONAL MODELS ON TQM

Edward W. Deming, originally an American statistician who was invited to cooperate with the Japanese Government in the 1950s (Deming, 1982), did an outstanding job with the JUSE (Japanese Union of Scientists and Engineers) to help this nation to recover after the war. His activities were recognized by establishing a Japanese Award on TQM which took his name.

The Deming Prize on TQM is probably the most famous quality award of the world. Originally it was dedicated only to Japanese companies, but it is being offered today as a worldwide opportunity. The award is based on a model which basically refers to the previously mentioned essentials.

In 1987, George Bush, President of the United States, stated that 'quality management is not only a strategy. It has to be a new working style, even a new thinking style. Dedication to quality and excellence is more than a business. It is a way of living, an opportunity to provide the society with the best of ourselves' (Merli, 1995: 197).

The Malcolm Baldrige National Quality Award (MBNQA) was created by a Public Law of the United States on August 20, 1987. It took the name of the Secretary of State, killed in an accident. Since then, it is the model used to grant yearly Prizes and Awards in the United States. It was designed with very much in common with the Deming Model.

The European Foundation for Quality Management is a non-profit organization, created in 1988 by 14 European organizations which were concerned with the sustainable growth and competitiveness of organizations in Europe. Since the beginning, it is committed to promote quality management as the way to excellence. As discussed in the introduction, we shall focus on this model in the following pages.

EFQM's mission is 'to be the driving force for sustainable excellence in Europe; its vision is a world in which European organizations excel' (EFQM, 1999: 3).

With the support of the European Organization for Quality and the European Commission (Directorate-General III), EFQM launched in October 1991 the European Quality Award, based on the model developed during the previous 2 years. In October 1992, King Juan Carlos I of Spain presented European Quality Prizes and the Award for the first time, at the EFQM Forum in Madrid.

During recent years, a number of National and Regional Quality Awards have been launched in different European countries; most of them use the EFQM Model of Excellence as their primary reference.

Concerning the types of prizes and awards, the EFQM has now a variety of recognition for different types of organizations, depending on size and industry. For example, the original large organization prizes and award has been extended to company divisions and Small and Medium Sized Enterprises (for the sake of simplicity, we shall refer in this entry to this SME version of the Model); on the other hand, the EFQM offers every year prizes and an award to the Public Sector.

On top of being used to assess organizations for these European Prizes and Awards, the Model has become an outstanding tool for all kinds of organizations to self-assess, determine their strengths and areas for improvement, and develop improvement plans based on them.

Today, the EFQM has a membership of almost 1000 organizations from most European countries and a wide activity sector coverage. This foundation is not only the owner of the EFQM Model, managing the European Quality Award process, but also is well recognized for the services it provides to its members and the community.

THE EFQM MODEL

As mentioned in the preceding section, we shall be referring to the Model in the SME version: it covers the same essential excellence elements as the Model for larger organizations and uses the same structure. However, the definitions and descriptions have been slightly modified and the criteria subdivided into fewer parts. For the purpose of this entry, we thought the SME version was easier to understand and transmits the same philosophy. Details on this Model can be found in the EFQM *Small and Medium Sized Enterprises*, Application Brochure, 2000.

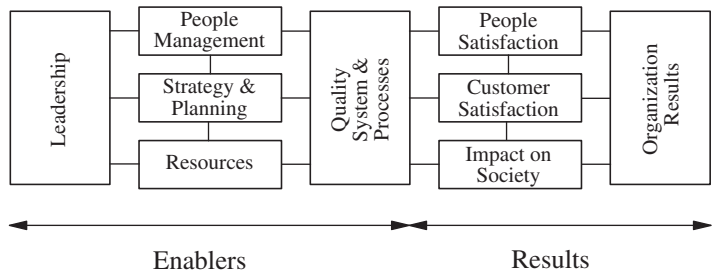

Figure 1. The EFQM Model for small and medium sized organizations.

Figure 1 shows the structure of the Model. The underlying theme is that an organization will only achieve better results if it is able to motivate people to commit to the improvement of everything they do, through self-assessment and evaluation.

The Model's nine boxes represent the criteria used to assess an organization's progress towards excellence, grouped into *enablers* and *results*. Table 1 shows the maximum number of points for each criteria that the EFQM could grant to the organization, when it applies to the European Award. The equivalent percentages indicate the criterion's relative importance to the whole.

To most organizations, *results* are often the most important aspect. The Model emphasizes that the underlying processes, methods, and procedures must be considered, because they ultimately lead to the results. As a result, customer and employee satisfaction as well as impact on society are achieved through leadership, driving strategy and planning, people management, the management of resources, and the quality system and processes, leading ultimately to the improvement of the final organization results.

The four *results* are the consequence of the five *enablers*: these describe how those results are being achieved and are therefore a better indicator for the future.

In the following paragraphs, we shall review the main aspects of each criterion.

Leadership

This criterion deals with behaviour and actions of the executive team and all other managers inspiring, supporting and promoting a culture of Total Quality Management.

Leadership has to be analysed, on one side, in terms of how the management demonstrates that it is committed to TQM and, on the other side, how actively they drive improvement within the organization and are involved with stakeholders and other external organizations.

Examples of both areas are: the way they develop values and expectations and act as role models for these values; how they prioritize, fund, organize and support improvement activities within the organization; and how they manage relationships with customers, suppliers, and other external organizations.

Strategy and Planning

Strategy and Planning has to do with the way the organization formulates, deploys, reviews and turns strategies into action plans.

The formulation based on relevant and comprehensive information, the communication and implementation and the updating and improving of those strategies and plans are the parts of this criterion.

For instance, it is important that information from customers, suppliers and other people, including the employees, has been considered; it is key that the plans are shared within the organization; on the other hand, these plans and strategies have to be reviewed and modified when necessary.

People Management

Human resources have to be managed. The organization has to release the full potential of its people.

On one side, it has to develop and review people plans such as recruitment, training, objective setting, etc. On the other hand, it has to ensure empowerment of its people, through stimulation and involvement in continuous improvement activities, for example.

Resources

This criterion means the management of other resources effectively and efficiently, such as financial, information, suppliers, materials and other resources.

The allocation and use of financial resources, the assurance of the accessibility, security and accuracy of information, the supplier relationships or the use of buildings and equipment are examples of the areas to be analysed in this criterion.

Quality System and Processes

This criterion involves delivering value for customers through management of the organization's quality system and processes.

Areas to be covered in this criterion are the way the organization focuses on customers, how it manages the quality system, the management of key processes, and the way the organization ensures continuous improvement.

Customer Satisfaction

Once we have reviewed the *enabler* part of the Model (the previous five criteria), Customer Satisfaction is the first of the *results* of the organization. In fact, it is the most important criterion in this Model, taking into account that it represents twenty per cent of the total weight.

This criterion and the next two are similar in structure: perceptions, on one side, and additional measurements relating to the satisfaction, on the other.

For example, perceptions on overall image, services loyalty, etc. are to be taken into account.

Table 1. Number of points per criterion and percentages of participation of each criterion of the EFQM Model

Criteria	Points	%
Leadership	100	10
People management	90	9
Strategy and planning	80	8
Resources	90	9
Quality system & processes	140	14
People satisfaction	90	9
Customer satisfaction	200	20
Impact on society	60	6
Organization results	150	15
Totals	1000	100

As far as other measurements are concerned, consider the following examples: defect, error and rejection rates, number of complaints, duration of relationship, etc.

People Satisfaction

The perceptions of the employees concerning the organization, such as the satisfaction with the working environment, the communications or the recognition and training opportunities, are some of the examples to be explored.

Absenteeism, sickness, complaints or turnover of employees are examples of other indirect measurements to evaluate the satisfaction of the employees.

Impact on Society

This criterion deals with the results the organization is achieving in satisfying the needs and expectations of the community in which it is located.

Areas such as reduction and prevention of noise and pollution, active involvement with communities, etc. are some of the views the society has of the organization, usually obtained through surveys and other means.

Organization Results

Financial and other measures of the organization's performance are the content of this criterion. The results the organization is achieving are in relation with its planned objectives and in satisfying the needs and expectations of everyone with a financial interest in the organization.

Profit, loss and budget results, balance sheet items and non-financial areas such as cycle times for key processes are a few areas which could be addressed.

Criteria Attributes

When the EFQM assess an application for the European Award or when an organization gets involved in a self-assessment process, it scores each of the parts or sub-criteria mentioned above looking at a number of attributes.

Enablers

The parts of the first five criteria (Leadership, Strategy and Planning, People Management,

Table 2. Range of benefits found by organizations by the application of the EFQM Model (EFQM, 1999: 9)

- Provides a highly structured, fact-based approach to identifying and assessing an organization's strengths and areas for improvement and measuring progress periodically
- Educates people on the fundamental concepts and framework for managing and improving the organization and how it relates to their responsibilities
- Integrates the various improvement initiatives into normal operations
- Facilitates comparisons with other organizations of a similar or diverse nature, using a set of criteria that is widely accepted across Europe, as well as identifying and allowing for the sharing of 'good practice' within an organization
- It offers organizations an opportunity to learn: to learn about the organization's strengths and weaknesses, about what 'excellence' means to the organization, about the organization's progress, how far it still has to go, and how it compares with other organizations

Resources and Quality System and Processes) are assessed looking from two perspectives: the *approach* the organization utilizes to satisfy the requirements of the corresponding sub-criteria, on one side, and the *deployment* or the extent this approach is implemented, on the other side.

Results

Each of the parts of the results (Customer Satisfaction, People Satisfaction, Impact on Society and Organization Results) are assessed, as well, looking at two attributes: the *magnitude* of the corresponding result (to what extent it is improving and compares favourably with own objectives and the results of other organizations); and the *scope* of those results, which refers to the extent the result covers all relevant areas of the activities and shows a full range of data.

Recently, the EFQM has developed a concept called RADAR, which encompasses those attributes in a very appealing way. RADAR is the acronym for Results, Approach, Deployment, Assessment and Review. RADAR is not only a good reminder of the attributes, but it underlines a very important subject: the importance to assess and review the approaches.

SELF-ASSESSMENT AND PERFORMANCE IMPROVEMENT

Adoption of the process of self-assessment is the EFQM's recommended strategy for improving performance (EFQM, 1999: 8).

Self-assessment is a comprehensive, systematic, and regular review of an organization's activities and results referenced against the EFQM Model. Today, many organizations are using the Model for this purpose, determining their strengths and areas subject to improvement.

Organizations carry out this cycle of evaluating and taking action repeatedly, so that they can achieve a sustained improvement. The most advanced have integrated self-assessment in the regular organization's planning cycle.

The EFQM reports, in the above, mentioned brochure, some of the benefits the organizations are finding with self-assessment (see Table 2).

FUTURE PERSPECTIVES

The well known American quality *guru*, Edward Deming (Deming, 1982) mentions that organizations will be able to reach a point of excellence when every employee is behaving like a *little scientist*, performing the activities following the cycle of observing, reflecting, checking and acting. The idea is that, when you have a critical mass of personnel capable of doing that, the improvement process is sustained.

Learning has always been key to quality. Japanese expert Ishikawa states that quality starts and ends with education (Ishikawa, 1990). The mentioned improvement cycle has embedded the learning in itself. In fact, the EFQM Model implies that feedback of the results (assessment and review) improves approaches by innovation and *learning*.

As a consequence of the above comments, it is evident that future perspectives suggest a competitive scenario where people (at least a critical mass) are fully committed and organizations are involved in a continuous learning process. Only in this way will they survive by maintaining a competitive position.

In summary, the future of organizations will only look at those which are capable of committing people to a self-assessment.

CONCLUSIONS

Total Quality Management is a key management and assessment strategy which is here to stay, providing a sound base for the future. It is not a revolutionary tool because its contents are pure logic. Importance does not lie in the theory, but in the practice: apply and do what you believe should be done in an orderly and structured way.

To help in the application of the self-assessment process, TQM Models in general, and the EFQM Model in particular, are practical tools, ready made and proved by many organizations with significant results. The psychological community can benefit from them in most organizational settings.

TRAIT–STATE MODELS

INTRODUCTION

Many psychological attributes have state as well as trait versions. This is most obvious for mood states. A classical example is Spielberger's state and trait anxiety. State anxiety is assessed via items in which the *actual mood states* have to be rated ('right now I feel . . .') whereas trait anxiety is assessed by items asking for the *general mood state* ('in general I feel . . .'). However, it is interesting to note that the concept of *states* was introduced to personality research only during the 1960s and 1970s. By contrast, the concept of *traits* has guided personality research from its very beginning, even though the distinction between states and traits appears to be as old as thinking about human mind and behaviour.

Traditionally, some psychological properties are classified as states, such as well-being and feeling anxious, while others are said to be traits such as extraversion, neuroticism, etc. However, the more general approach is certainly to assume that each psychological property is *statelike* to some degree and therefore also *traitlike* to some degree. Observed mood states are not only due to (bio-psycho-social) situations but also depend to some degree on permanent characteristics of the person. Similarly, observed trait measures not only depend on permanent characteristics of the person, but are also due to situations to some

degree. This is the substantive background for latent state–trait (LST) theory and its associated latent state–trait models to be described in the following sections.

LATENT STATE–TRAIT THEORY

In the 1990s, LST theory has been introduced defining *states* (of whatever variable) as a property of a *person-in-a-situation* and *traits* as a property of a *person*. Furthermore, specific structural equation models for longitudinal data have been developed that can be used to disentangle state and trait components of whatever variable.

Originally, LST theory was developed as a generalization of classical test theory (CTT), designed to take into account that psychological assessment does not take place in a situational vacuum. Hence, from a substantive perspective, LST theory may also be viewed as a methodological development coping with arguments raised in the person–situation debate. Whereas in CTT, aside from measurement error, there is only one single factor (persons) determining the variance of an observable variable, LST theory explicitly assumes two factors instead: persons and situations. Even though the standard models of LST theory are not designed to disentangle situation effects and the effects of interaction between persons and situations, interaction effects are an integral part of the theory.

The core of LST theory consists of two decompositions: (a) the decomposition of any observable variable into *latent state* and *measurement error* variables, and (b) the decomposition of any latent state into *latent trait* and *latent state-residual* variables, the latter representing situational and/or interaction effects. Latent state and latent trait variables are defined as special conditional expectations. A score of a *latent state variable* is defined to be the conditional expectation of an observable variable *given a person-in-a-situation*, whereas a score of a *latent trait variable* is the conditional expectation of this observable variable *given a person*.

The theory also comprises the definition of *consistency*, *occasion specificity*, *reliability*, and *stability* coefficients. The consistency coefficient is the proportion of variance of an observable variable that is due to the latent trait. Hence, it measures the degree to which the observable variable is *traitlike*. In contrast, the occasion-specificity coefficient is the proportion of variance of an observable variable due to the situation and/or the person–situation interaction on the occasion of measurement considered. Hence, it measures the degree to which the observable variable is *statelike*.

The reliability coefficient is the proportion of variance of an observable variable determined by the differences between the persons, situations, and the interaction between persons and situations. Because of the additivity of the variances of the latent trait and latent state-residual variables, the consistency and occasion-specificity coefficients add up to the reliability coefficient. If one intends to measure a trait, the consistency coefficient should be high and the occasion-specificity coefficient should be low. If one intends to assess a mood state, it should be the other way around. In both cases, however, reliability should be high.

LATENT STATE–TRAIT MODELS

The first LST models were published by Steyer and his colleagues in the late 1980s. However, there were also independent developments yielding the same class of models by Dumenci and Windle (1996), Marsh and Grayson (1994), as well as Ormel and Schaufeli (1991). Recently, Tisak and Tisak (2000) outlined the relationship of LST models to growth curve models. In the 1990s, LST models have been developed and applied in some dozens of papers (see Steyer, Schmitt & Eid, 1999, for an overview over applications and research questions to be studied via LST models).

LST models are defined by assumptions about the basic variables of LST theory. These assumptions can differ in their complexity. The assumptions defining specific models serve to identify the theoretical parameters such as reliability, consistency, and occasion specificity. Many of these models have already been described in some detail by Steyer, Ferring, and Schmitt (1992). All these models turn out to be special structural equation models.

Singletrait–Multistate Models

In the singletrait–multistate model we assume that there is a common single latent trait variable

determining the observable variables within and across each of several occasions of measurement. This trait variable is constant over time. That is, it is assumed that there is no trait change. From the perspective of Developmental Psychology, this means that there is no development. However, the model allows for change in the latent state variables between occasions of measurement. These changes are due to the fact that bio-psycho-social situations fluctuate between occasions of measurement for a given person affecting the latent state variables and, therefore, also the observable variables.

Multitrait–Multistate Models

If there are not only situation-driven fluctuations in the latent states but also trait change, we need LST models assuming invariant traits within at least two periods of time, but allowing for trait change between the two periods. In such a model we would introduce a common latent trait for each period of time. Several latent traits might also be useful if observable variables do not measure exactly the same state, for example, by parallel test forms or parallel (perfectly unidimensional) items. In these (frequently occurring) cases we may introduce variable-specific or, in item response models, item-specific latent trait variables that might be invariant over time (Marsh & Grayson, 1994). An alternative is to introduce variable-specific (or item-specific) residual factors (method factors) (Eid, 2000), the variance of which reflect the degree of heterogeneity of the variables or items considered. To summarize, several traits may be necessary for two reasons: (a) heterogeneity of the observable variables and (b) trait change over time. A model incorporating both aspects has been presented by Eid and Hoffmann (1998) studying trait change in the interest in radioactivity before and after the Chernobyl catastrophe.

True Change Models

Whereas state change implicitly occurs in all models described above, trait change is possible only in models that explicitly incorporate different traits for different periods of time. Sometimes we are interested in explaining inter-individual differences in intra-individual change. Steyer, Partchev, and Shanahan (2000) showed how to specify a structural equation model in such a way that true intra-individual change scores between neighboured occasions are the values of endogenous variables that may be explained by exogenous variables and other endogenous variables. Similarly, they also introduced endogenous latent change variables, the values of which are the true intra-individual change scores between occasion one (baseline) and any other occasion. Both classes of models may be used to study why some individuals change more (or less) than others, for example after a therapy, after an educational intervention, or in the normal developmental process. Note that these models may also be applied in probit (Eid & Hoffmann, 1998) and logistic IRT models (Steyer & Partchev, 2000).

FUTURE PERSPECTIVES AND CONCLUSIONS

LST models are just one example of how statistical models can be designed to reflect the complexity of psychological assessment. What is most fascinating and will certainly inspire future developments is that the models presented in the more recent papers mentioned above (Steyer & Partchev, 2000; Steyer, Partchev & Shanahan, 2000) comprise submodels on the individual level as well as submodels on the group level. The *individual level* is modelled via the latent variables, the values of which are scores of individuals (here persons and persons-in-situations). The *group level* is modelled via the submodel for the expectations. Models consisting of both levels bear a new opportunity for psychology: a chance to reunite Differential Psychology and General Psychology.

TRIARCHIC INTELLIGENCE COMPONENTS

INTRODUCTION

In the triarchic theory of human intelligence, information-processing components are applied to experience in order to adapt to, shape, and select environments (Sternberg, 1985, 1997, 1999). A common set of universal processes underlies all aspects of intelligence.

Metacomponents, or executive processes, plan what to do, monitor things as they are being done, and evaluate things after they are done. *Performance components* execute the instructions of the metacomponents. *Knowledge-acquisition components* learn how to solve problems or simply to acquire declarative knowledge in the first place.

Analytical intelligence is invoked when components are applied to fairly familiar kinds of problems abstracted from everyday life; *creative intelligence* when the components are applied to relatively novel kinds of tasks or situations; and *practical intelligence* when the components are applied to experience to adapt to, shape, and select environments.

MEASURING ANALYTICAL INTELLIGENCE

Analytical kinds of problems, such as analogies or syllogisms, can be analysed componentially (Sternberg, 1983), with response times or error rates decomposed to yield their underlying information-processing components. Componential analysis reveals information-processing origins of individual differences in intelligence. The general strategy of such research is to (a) specify an information-processing model of task performance; (b) assign a mathematical parameter to each information-processing component; and (c) construct cognitive tasks administered in such a way that it is possible through mathematical modelling to isolate the parameters of the mathematical model. In this way, several sources of important individual or developmental differences are isolated: (a) the performance components used; (b) time to execute each component; (c) susceptibility of each component to error; (d) strategy for combining the components; (e) mental representations upon which the components act.

What are some results? Although children generally became quicker in information processing with age, not all components were executed more rapidly with age. The encoding component first shows a decrease in component time with age and then an increase. Apparently, older children realize that their best strategy is to spend more time in encoding the terms of a problem so that they later would be able to spend less time in operating on these encodings. Moreover, better reasoners spend relatively more time than do poorer reasoners in global, up-front metacomponential planning, when they solve difficult reasoning problems. Poorer reasoners, on the other hand, spend relatively more time in local planning. Presumably, better reasoners recognize it is better to invest more time up front so as to be able to process a problem more efficiently later on.

In one set of studies on knowledge-acquisition components, individuals figured out meanings of unknown words in sentences; for example, 'The *blen* rises in the east and sets in the west' (Sternberg, 1987). A componential model was able to predict word difficulty very well, and scores on the decontextualization task provided excellent prediction of individual differences in vocabulary skills.

MEASURING CREATIVE INTELLIGENCE

Creative intelligence is measured by convergent or divergent problems assessing how well people can cope with relative novelty.

In work with convergent problems, participants received novel kinds of reasoning problems that had a single best answer. For example, participants might be told that some objects are green and others blue; but still other objects might be grue, meaning green until the year 2000 and blue thereafter, or bleen, meaning blue until the year 2000 and green thereafter (Sternberg, 1982; Tetewsky & Sternberg, 1986). Their task was to predict future states from past states, given incomplete information. In another set of studies, 60 people were given more conventional kinds of inductive reasoning problems. But the problems had premises preceding them that were either conventional (dancers wear shoes) or novel (dancers eat shoes). The participants had to solve the problems as though the counterfactuals were true (Sternberg & Gastel, 1989a, b).

The more novel the test items, the higher the correlations of our tests with scores on successively more novel conventional tests. Some components better measured the creative aspect of intelligence than did others. For example, in the 'grue–bleen' task mentioned above, the component requiring people to switch from conventional green–blue thinking to grue–bleen thinking and then back to green–blue thinking again was a particularly good measure of the ability to cope with novelty.

In work with divergent reasoning problems having no one best answer, people created two each of various kinds of products (Sternberg & Lubart, 1995) in the realms of writing, art, advertising, and science. They wrote very short stories with a choice of titles, such as 'The Octopus's Sneakers'. They produced art compositions with titles such as 'Earth from an Insect's Point of View'. They created advertisements for products such as a brand of doorknob. And they solved problems such as of how humans might detect extraterrestrial aliens among them who are seeking to escape detection. What was found?

First, creativity comprises five resources and an external one: intelligence, knowledge, thinking styles, personality, motivation and environmental forces. Second, creativity is relatively although not wholly domain-specific. Correlations of ratings of the creative quality of the products across domains were lower than correlations of ratings and generally were at about the 0.4 level. Third, correlations with conventional ability tests were generally modest to moderate, but were higher to the extent that problems on the conventional tests were non-entrenched. For example, correlations were higher with fluid than with crystallized ability tests.

PRACTICAL INTELLIGENCE

A key concept has been that of tacit knowledge, which is what one needs to know in order to work effectively in an environment that one is not explicitly taught and that often is not even verbalized (Sternberg et al., 2000).

Tacit knowledge has been measured using work-related problems that present problems one might encounter on the job. Tacit knowledge has been measured for both children and adults, and

among adults, and for people in over two dozen occupations, such as management, sales, academia, teaching, secretarial work, and the military. In a typical tacit-knowledge problem, people are asked to read a story about a problem someone faces and to rate, for each statement in a set of statements, how adequate a solution the statement represents. For example, in a paper-and-pencil measure of tacit knowledge for sales, one of the problems deals with sales of photocopy machines. A relatively inexpensive machine is not moving out of the show room and has become overstocked. The examinee is asked to rate the quality of various solutions for moving the particular model out of the show room. In a performance-based measure for sales people, the test-taker makes a phone call to a supposed customer, who is actually the examiner. The test-taker tries to sell advertising space over the phone.

Results are, first, that practical intelligence as embodied in tacit knowledge increases with experience, but it is profiting from experience, rather than experience per se, that results in increases in scores. Second, subscores on tests of tacit knowledge – such as for managing oneself, managing others, and managing tasks – correlate significantly with each other. Third, scores on various tests of tacit knowledge, such as for academics and managers, are also correlated fairly substantially (at about the 0.5 level) with each other. Thus, fourth, tests of tacit knowledge may yield a general factor across these tests. However, fifth, scores on tacit-knowledge tests typically do not correlate with scores on IQ tests, whether the measures used are single-score measures of multiple-ability batteries. In some cases, the correlation is negative (Sternberg et al., 2001). Thus, any general factor from the tacit-knowledge tests is not the same as any general factor from tests of IQ (suggesting that neither kind of *g* factor is truly general, but rather, general only across a limited range of measuring instruments). Sixth, scores on tacit-knowledge tests predict performance on the job as well as or better than does IQ. Seventh, scores on tests of tacit knowledge for management were the best single predictor (over IQ, personality traits, cognitive styles) of performance on a managerial simulation. Eighth, tacit knowledge for military leadership predicted ratings of leadership effectiveness, whereas IQ and tacit knowledge for managers did not significantly predict the ratings of effectiveness.

FACTOR ANALYSES TESTING THE TRIARCHIC THEORY AS A WHOLE

Four separate factor-analytic studies support the construct validity of the theory of successful intelligence.

One study in the US (Sternberg, Grigorenko, Ferrari & Clinkenbeard, 1999) used the Sternberg Triarchic Abilities Test (STAT – Sternberg, 1993), which comprises 12 subtests. There were four subtests each measuring analytical, creative, and practical abilities. For each type of ability, there were three multiple-choice tests and one essay test. The multiple-choice tests, in turn, involved, respectively, verbal, quantitative, and figural content. Consider examples:

1. Analytical–Verbal: Figuring out meanings of neologisms (artificial words) from natural contexts. Students see a novel word embedded in a paragraph, and have to infer its meaning from the context.
2. Practical–Figural: Route planning. Students are presented with a map of an area (e.g. an entertainment park) and have to answer questions about navigating effectively through the area depicted by the map.
3. Creative–Quantitative: Novel number operations. Students are presented with rules for novel number operations, for example 'flix', which involves numerical manipulations that differ as a function of whether the first of two operands is greater than, equal to, or less than the second. Participants have to use the novel number operations to solve presented maths problems.
4. Analytical–Essay: Students analyse the use of security guards in high schools: what are the advantages and disadvantages and how can these be weighed to make a recommendation?

As predicted, confirmatory factor analysis on the data yielded separate and uncorrelated analytical, creative, and practical factors. The multiple-choice analytical subtest loaded most highly on the analytical factor, but the essay creative and practical subtests loaded most highly

on their respective factors. Thus, measurement of creative and practical abilities probably ideally should be accomplished with other kinds of testing instruments that complement multiple-choice instruments.

A second study used a revised version of the STAT (Grigorenko, Gil, Jarvin & Sternberg, 2000). This test supplements the creative and practical measures mentioned above with performance-based measures. For example, creative abilities are additionally measured by, for example, having people do captions for cartoons and using computer software to design a variety of products, such as greeting cards and a company logo. Practical skills are additionally measured, for example, by solving everyday problems presented by means of films, and by a situational-judgement inventory.

The creativity tests were moderately correlated with each other, the practical tests, highly correlated with each other. The two kinds of tests were distinct from one another, however. Exploratory factor analysis reveals that the performance-based assessments tend to cluster separately from multiple-choice assessments measuring the same skills (similar to our earlier findings of essay measures tending to be distinctive from multiple-choice measures).

In a third study in the US, Finland, and Spain, the multiple-choice section of the STAT was used to compare five alternative models of intelligence, again via confirmatory factor analysis. A model featuring a general factor of intelligence fit the data relatively poorly. The triarchic model, allowing for intercorrelation among the analytic, creative, and practical factors, provided the best fit to the data (Sternberg, Castejón, Prieto, Hautakami & Grigorenko, 2001).

In a fourth study, Grigorenko and Sternberg (2001) tested 511 Russian school children (ranging in age from 8 to 17 years) as well as 490 mothers and 328 fathers of these children. They used entirely distinct measures of analytical, creative, and practical intelligence.

In this study, exploratory principal-component analysis for both children and adults yielded very similar factor structures. Both varimax and oblimin rotations yielded clearcut analytical, creative, and practical factors for the tests. Thus, with a sample of a different nationality (Russian), a different set of tests, and a different method of analysis (exploratory rather than confirmatory analysis), this again supported the theory of successful intelligence.

FUTURE PERSPECTIVES

The Center for the Psychology of Abilities, Competencies, and Expertise at Yale is currently further testing the triarchic theory in major ways. First, we are doing instructional studies in several different subject-matter areas at a variety of grade levels with students all across the United States in order to determine whether triarchic teaching improves performance. Second, we are doing instructional studies with military officers in order to determine whether the methods work with adults. Third, we are doing studies to determine whether the triarchic ability patterns necessary for success in school and in life change over the course of the life span, emphasizing especially childhood and early adulthood.

CONCLUSIONS

Conventional tests yield a general factor of intelligence because they are limited in the scope of what they measure. When tests are augmented to include measurement of creative and practical abilities, separate creative and practical factors emerge. Instructional studies show that triarchic teaching and assessment can improve school performance.

TYPE A: A PROPOSED PSYCHOSOCIAL RISK FACTOR FOR CARDIOVASCULAR DISEASES

INTRODUCTION

One of the main goals of research in psychology and health has been to find a reliable way of identifying those individuals who might have a higher risk of developing cardiovascular diseases. Focusing on personality research, since the late 1950s, a higher incidence of cardiovascular disorders, and a possible related enhanced cardiovascular responsivity to environmental stimuli, has been linked to distinctive patterns of behaviour mainly characterized by specific ways of coping with stress. More specifically, the Type A Behaviour Pattern (TABP), valued as an independent risk factor in the aetiology of cardiovascular disease (CVD), and, more recently, hostility – defined as a wide behavioural complex – represents the most fruitful area of

study in the search for behavioural aspects that are related to increased CVD morbidity and premature mortality.

From this perspective, this entry presents the state of the art of research on Type A and its potential role in the onset and development of cardiovascular diseases.

THE TYPE A BEHAVIOUR PATTERN

Over the past few decades an increasing amount of research on psychosocial factors associated with the development of cardiovascular disorders has been carried out. In this context, and mainly from the pioneering research of Friedman and Rosenman (1959), a behavioural style has been identified, the so-called Type A Behaviour Pattern, characterized by the following behavioural manifestations: competitive achievement striving, hostility, aggressiveness, rapid and explosive speech, and a sense of time urgency and impatience.

From the large existing evidence, pointing out that these behavioural manifestations are associated with the development of coronary heart disorders, nowadays it is well accepted that such a behavioural style is an independent risk factor for coronary heart disease with the same weighting as traditional risk factors such as serum cholesterol, systolic blood pressure or smoking.

TABP Assessment

As it is widely recognized, TABP assessment is mainly accomplished by the *Structured Interview* (SI; Rosenman, 1978) and the *Jenkins Activity Survey for Health Prediction* (JAS; Jenkins, Zyzanski & Rosenman, 1979), although they represent rather different configurations of TABP dimensions which are, often, differently related to health and psychosocial variables. While JAS contents are mostly concerned with achievement and work issues, basically lacking in sufficient TABP hostility representation, SI directly elicits Type-A's anger, dominant and speed-prone responses. This might be one of the possible explanations for SI's better capacity of cardiovascular disease (CHD) prediction, although, despite early conclusions, both ways of assessment seem to be equally reliable predictors of cardiovascular reactivity (Lyness, 1993).

On the other hand, most of the evidence concerning TABP psychological functioning is JAS derived. A Spanish adaptation of this questionnaire (JASEH; Bermúdez, Pérez-García & Sánchez-Elvira, 1991) was developed trying to overcome shortcomings of TABP self-reports, in general, and those of the JAS in particular. In order to improve its predictive validity, hostile Type A contents were subsequently increased as had been repeatedly demanded. This Spanish version presents good psychometric qualities and has demonstrated to be a good predictor of A–B (global and component scales) differences.

Mechanisms Linking TABP and CVD

Although different mechanisms have been considered as potential links between this behaviour pattern and CHD, most research has focused on the psychophysiological hypothesis. This hypothesis asserts that Type A individuals display greater cardiovascular and neuroendocrine reactivity and/or slower recovery of their physiological responses when exposed to various situations. In any case, these two aspects of physiological reactivity (response amplitude and duration of response-recovery) are claimed to be relevant to a possibly pathophysiological process (coronary artery atherosclerosis) underlying the clinical manifestations of CVD (myocardial infarction, angina pectoris, etc.).

Recent studies however lack consistency regarding both the association TABP–CVD (Haynes & Matthews, 1988; Miller et al., 1991) and the psychophysiological mechanism suggested (Harbin, 1989; Lyness, 1993; Miller et al., 1991). In view of these discrepancies, we can appreciate more accurately the current state of affairs; research on TABP might not, certainly, be at the end of the journey, but rather at a turning point which has been called 'the Type-A second generation research' (Williams, 1989).

TABP DIMENSIONALITY

The reviews previously mentioned sustain that relevant moderators may help to clarify inconsistent findings in TABP research. New inquiries directed to the understanding of TABP cardiovascular hyperreactivity and its relationships to

CVD have been enunciated. Perhaps the most intriguing and relevant inquiries, in terms of TABP conceptualization and predictive validity, are those referring to the multidimensional nature of the TABP construct. In other words, a gradual and more accurate approach to the understanding of TABP functioning has led to some important conclusions regarding its conceptualization as a homogeneous psychological construct: not only do TABP components not seem to function always in the same direction, but, also, they can predict just the opposite. TABP unidimensionality and the utility of a single score derived from a global assessment have been, thus, seriously questioned and new methodological and empirical strategies, as well as component-related specific hypotheses, have been developed. Individuals should not be assessed on global Type A, but on its components, in order to determine their specific contributions; moreover, TABP research should identify significant clusters, patterns or profiles of underlying behavioural components, taking into account that an equal TABP score may be reflecting heterogeneous kinds of Type A individuals (Thoresen & Powell, 1992).

In this sense, two distinctive core dimensions within TABP have been consistently identified in terms of their predictive power in different psychosocial and physiological fields: a *Hostile–Irritable–Impatient* dimension (also called 'trait dysphoric' and high-reactive Type A) and a *Competitive-Hard driving–Achievement Striving* dimension (also called 'low-reactive Type A') (Svebak et al., 1992).

Empirical research shows, then, on the one hand, a *Competitive Type A dimension* defined by the following psychosocial and psychological functioning characteristics: absence of negative emotional correlates such as depression, anxiety or emotional susceptibility, and also absence of hostility/anger, and disease or stress symptomatology (especially when the effects of the other TABP dimension are controlled); extraversion, optimism, and self-esteem correlates; active coping and planning activity under stress; better performance in different tasks, even under interfering conditions; more productivity at work and higher professional status and annual incomes. On the other hand, a *Hostile–Impatience Type A dimension* which represents a different combination of characteristics that can be mainly described as follows: clear and strong negative emotional correlates such as depression, anxiety, neuroticism or emotional susceptibility, hostile/angry manifestations, and disease or stress derived symptomatology; both avoidance and active confrontation under stressful situations and negatively affected performance under stressful instructions or disruptive conditions such as in the presence of interfering stimuli. Finally, both dimensions report experiencing more negative life events, in general.

COMPONENTS' DIFFERENTIAL TOXICITY

This componential perspective has, also, important implications from a health standpoint. TABP dimensions have proved to be predictive of different health outcomes in both men and women. Research on the potential toxicity of TABP components tends to conclude that not all its characteristics might necessarily be *coronary-prone* behaviours, but just those involved in the hostile–impatient dimension. Causal linked designs reveal a higher CVD risk for hostile–impatient Type-As (Houston et al., 1992; Julkunen, Idänpäan-Heikkila & Saarinen, 1993). In parallel, the hostile–impatience TABP dimension has also been the main one related to higher levels of cardiovascular reactivity displayed in different stressful situations (Svebak et al., 1992). These data are congruent with the extensive and more recent body of literature concerned with research into hostility and health, in general. In this sense, hostility and anger have proved to be coronary-prone behaviours and clear predictors of cardiovascular reactivity to stress, although a further refinement of these relevant psychological constructs, within a multidimensional approach, is urgently required in order to clarify the conceptual unspecificity and ambiguities that characterize the assessment and research in this field.

However, there is some evidence, also, about the predictive value of Competitiveness concerning health outcomes and cardiovascular reactivity, although this is less clear than for Hostility/Impatience (Svebak et al., 1992). These inconsistencies demand, then, (1) a more detailed analysis of TABP dimensions with respect to their psychological and physiological functioning and

their psychosocial characteristics, and (2) a better understanding of different TABP profiles and their transactions with the environment (Thoresen & Powell, 1992).

Recent cluster analyses with data from the Western Collaborative Group Study (WCGS) suggest that, although only in an exploratory stage, there may be several patterns of components in CVD risk (Houston et al., 1992): two risk TABP profiles (a hostile profile and a pressured, controlling and social dominant one), some non-health related TABP profiles and, even, some healthy or inversely CVD-related risk profiles (mainly characterized by emotional and behavioural underreactivity to provocation).

FUTURE PERSPECTIVES AND CONCLUSIONS

In summary, perhaps some of the inconsistencies observed in past studies concerning TABP have been due to a failure in considering the heterogeneous nature of the TABP. Thus, a global score may have cancelled out the opposite and/or different directions of TABP components and the possibility of yielding significant results. The available evidence tends to confirm that the use of a componential approach on TABP research may certainly increase the proportion of explained variance in health outcomes. These new approaches would help to better clarify TABP cardiovascular reactivity and CHD relationships.

Current data about TABP dimensions point out the existence of two rather different Type As in terms of their predictive psychosocial and health values. A careful and detailed observation of each dimension could lead us to a tentative hypothesis about its possible underlying mechanism of psychological and physiological functioning. In this sense, it could be postulated that hostile/impatient and competitive profiles, being both Type As, are under the control of different patterns of activation processes. While the former would be representative of a *cognitive-emotional activation* highly linked to anxiety, negative moods, and particularly vulnerable to stressful, demanding and threatening situations, the latter would be representative of a *motivational mechanism* more linked to control and achievement striving (independently of real task demands), and less vulnerability to stress. Taking into account the psychological characteristics of both dimensions, a more pervasive, frequent and lasting physiological hyperreactivity pattern may be more characteristic of hostile–impatient Type As than Competitive ones, which could put them at a higher risk of CVD. This hypothesis encourages further examination of TABP profiles and their possible repercussions on health and well-being.

TYPE C: A PROPOSED PSYCHOSOCIAL RISK FACTOR FOR CANCER

INTRODUCTION

The Type C behaviour pattern, hypothesized to be related to the progression of cancer, was first elaborated and operationally defined in a study of psychosocial and epidemiological factors associated with malignant melanoma (Temoshok & Heller, 1981). Independently, British researchers had posed the question of whether there might be 'a Type C for cancer?' in an abstract published the previous year (Morris & Greer, 1980).

Assessment of Type C coping in the US has mirrored conceptualizations of how this pattern, when chronically engaged, may have negative implications for physiological and immunological functioning (Temoshok, 1987). This model was elaborated in subsequent iterations, which emphasized that the goal of coping is to maintain psychological–physiological homeostasis, and that the more closely a coping process resembles the inverted U-shaped function which characterizes homeostasis for most biological processes, the more likely it is to be adaptive and to be associated with positive health outcomes (Temoshok, 2000a). Theoretically, coping with stressors is most effective when all systems are working together in a coordinated and synchronous manner, unlike the Type C pattern in which physiological arousal is not recognized consciously, and underlying emotion is not expressed. There are two hypothetical pathways or sets of mechanisms by which Type C coping can have negative health implications, the psychosocial and the psychoneuroimmunologic (Temoshok, 1995), although it is likely that these pathways interact and synergize each other. This entry will describe the evolution of the Type C construct over the past 20 years, and summarize its concomitant assessment in studies of cancer and HIV progression (see Table 1).

ASSESSING TYPE C IN CONTRAST TO THE TYPE A BEHAVIOUR PATTERN

In studies conducted at the University of California San Francisco (UCSF) School of Medicine, Type C was operationally defined as a constellation of (a) cognitive proclivities (decreased awareness of needs, feelings, and bodily sensations, while attending to perceived needs of others), (b) verbal and non-verbal expressive patterns (repressing or not expressing emotion, particularly anger, while presenting a pleasant façade), and (c) specific coping and behavioural characteristics (unassertive, appeasing, denying or minimizing problems, compliant with external authorities; Temoshok & Dreher, 1992). An inattention to symptoms or indications that anything might be wrong was theorized to contribute to the behaviour of delay in seeking medical attention for suspicious lesions, which was found to be significantly associated with tumour thickness, the best prognostic indicator for malignant melanoma (Temoshok et al., 1984).

Table 1. Assessment of components of Type C in studies of cancer and HIV/AIDS

Assessment of Type C component		
Denial/minimization of health concerns.	Semantic differential ratings (by coders) of Type C versus Type A characteristics.	Non-assertiveness in complying with others' imposing request.
Dysynchrony between psychological self-reports and physiological stress responses to emotional stimuli.	Emotionally inexpressive (as rated from videotaped interviews).	Higher Type C scores on Vignette Similarity Rating Method.
Behaviour or medical outcome predicted		
Delay in seeking medical attention, thicker melanoma lesions.	Unfavourable immune changes associated with HIV progression.	
Lower self-report of perturbation combined with higher skin conductance distinguished melanoma patients from heart disease patients and controls.	HIV progression from asymptomatic status to AIDS or more advanced disease at 6 and 12 month follow-ups.	
	Study references	
More unfavourable melanoma prognostic indicators.	Temoshok et al., 1984 Kneier and Temoshok, 1984	
Fewer lymphocytes at site of primary melanoma lesion (poorer prognosis).	Temoshok et al., 1985 Temoshok, 1985	

Type C was conceived as equivalently maladaptive as the Type A pattern, but its polar opposite, with the theoretically adaptive Type B pattern forming the third point in this conceptual triangle of adaptation and health implications (Temoshok, 1987). Temoshok and her colleagues at UCSF adapted the Type A interview schedule, used in prospective studies to predict the development of coronary heart disease, and had raters assess videotaped patient interviews, using 17 semantic differential scales which contrasted descriptors of Type A (e.g. impatient, hostile) or Type C (e.g. passive, appeasing). Independent from the variable of delay in seeking medical attention, the semantic differential ratings of Type C versus Type A were significantly correlated with tumour thickness, the most important melanoma prognostic indicator, most strongly for patients under age 55 (Temoshok et al., 1985).

In a study of another immunologically mediated disease, HIV infection, a key aspect of the Type C coping pattern, non-assertiveness in complying with others' requests against one's own wishes, was associated with unfavourable changes in immune parameters relevant to HIV progression (Solomon, Kemeny & Temoshok, 1991).

ASSESSING PSYCHOLOGICAL–PHYSIOLOGICAL DYSYNCHRONY IN TYPE C

Another step in the assessment of Type C focused on the 'repressive' aspect of the Type C constellation. An earlier method to assess repression had contrasted responses to two scales, the Taylor Manifest Anxiety Scale (a trait measure based on reported anxiety symptoms), and the Marlowe–Crowne Social Desirability Scale (a measure of the tendency to respond in a socially desirable direction), to define 'repressors' as the group with low reported anxiety and high Marlowe–Crowne scores (Weinberger, Schwartz & Davidson, 1979). The problem with using this method in the UCSF studies was that melanoma patients assessed at the point of learning their biopsy results were found to be overtly anxious, the strength of the stressful situation overcoming any tendency to repress this emotion.

Therefore, Kneier and Temoshok (1984) devised a method to capture the dysynchrony observed in Type C individuals between their under-reported anxiety, measured as self-report of perturbation following presentation of

potentially disturbing statements on slides, and a hypothetically unattended-to and therefore unmodulated physiological stress response, as measured by skin conductance response (SCR). The Type C pattern of response was defined in this study as the sum of all conjoint responses in which the subject's SCR was above the mean SCR across all statements for that individual, in conjunction with a self-report of perturbation below that individual's mean self-report score. As hypothesized, melanoma patients had significantly more Type C dysynchronous response patterns, in contrast to cardiovascular disease patients who displayed the opposite pattern (higher reports of psychological perturbation in conjunction with lower SCR), while controls showed a pattern in which psychological and physiological reactivity were appropriately correlated (Kneier & Temoshok, 1984).

ASSESSING EMOTIONAL NON-EXPRESSIVENESS IN TYPE C

In order to understand potential mediating mechanisms by which a psychological variable could influence cancer progression, another study focused on an immune measure which is directly related to disease outcome in malignant melanoma: the number of lymphocytes at the base of the deepest invasion of the primary tumour, as rated microscopically by a pathologist. Patients' emotional expressiveness, rated across five highly inter-correlated verbal and non-verbal dimensions from videotaped interview segments concerning how they felt when first told they might have melanoma, was strongly and significantly correlated with having more lymphocytes at the base of the tumour (Temoshok, 1985). This study was important in identifying the inappropriately dampened expression of emotion as the pathogenic core of the Type C pattern.

THE VIGNETTE SIMILARITY RATING METHOD

The problem with the methods of assessing aspects of the Type C coping pattern, described above, is that they all involved a great deal of equipment, time, and/or personnel, in addition to a fair amount of demand on study participants. These factors limited the number of participants in any one study, with the consequent constraints on statistical power. Clearly, another method was needed. Thus, the Vignette Similarity Rating Method (VSRM) was developed by combining (1) a multidimensional scaling method which described a person according to similarity ratings along a number of dimensions with (2) descriptions of actual (but disguised) patients' stories from the book on Type C by Temoshok and Dreher (1992). These stories or vignettes had strong face validity, in that they elicited strong feelings of recognition by people with cancer and their loved ones. In the VSRM, three vignettes, each about 170 words, describe the emotional, cognitive, interpersonal, and behavioural reactions of a person (matched by gender to the subject) who is confronted with the diagnosis of an unspecified life-threatening disease. Each vignette presents these reactions according to a general mode or style of responding to stress: (a) hypothetically adaptive Active Coping (i.e. seeking information, asking questions of one's physician, seeking the support of family and friends, expressing feelings and needs); (b) hypothetically maladaptive Helpless/Hopeless Reaction (i.e. feeling overwhelmed, avoiding friends and family, giving up, not acting effectively); or (c) Type C (denying problems, presenting a pleasant façade to the world, not 'bothering' one's doctor with complaints, and not expressing needs or feelings to family and friends). The task for the respondent is to rate on a 1 to 5 (or 10) point scale, 'How similar do you think your reactions are to the reactions of (name of the person in the vignette)?' Higher ratings of similarity for a particular vignette indicate that a respondent identifies with that respective mode of coping. Each of the three vignettes is scored separately, yielding an Active Coping score, a Helpless/Hopeless Reaction score, and a Type C score.

The method has been shown to have high test–retest reliability, as well as high face, construct, and predictive validity (Temoshok, 2000a). In an Italian study, originally asymptomatic HIV+ individuals characterized as having Type C coping were more likely to develop symptoms of AIDS at 6 and 12-month follow-ups (Solano et al., 1993). A separate study of 200 HIV-1 seropositive but asymptomatic men and women by the same group found that higher baseline

Type C coping scores significantly predicted progression at 6 months and 12 months, among participants classified at baseline as having more compromised immunity (Solano et al., 2002). The vignettes to assess Active Coping and the Helpless/Hopeless reaction were significantly correlated in the expected directions with the UCLA Loneliness Scale, the Perceived Social Support Scale, and particularly with the Control and Commitment subscales of the Hardiness scale, suggesting that multi-dimensional components of coping have been embodied in these respective vignettes (Solano et al., 2002).

An important advantage of the VSRM is that the task of rating similarity to the emotions and behaviours of someone else, the person in the vignette, appears to minimize the typical Type C defensiveness (denial or repression) about reporting socially undesirable states and behaviours, which confounds assessment in scales composed of items which ask directly whether one feels or acts in certain ways. Another key feature which contributes to the method's validity is that the descriptions of how the person in the vignette copes are set in the context of a very relevant stressful situation (an unspecified life-threatening disease), in contrast to non-contextual coping items as they are presented on most self-report scales (Temoshok, 2000b).

DIFFERENTIATING TYPE C AND ITS MEASUREMENT FROM SIMILAR CONSTRUCTS

The individual who chronically experiences negative emotions and simultaneously has the tendency to inhibit self-expression has been defined as having a distressed or 'type-D personality' (Denollet, 1997). Studies by Denollet and his colleagues have found that type-D patients experience a chronic state of stress that may have an adverse effect on prognosis in the context of coronary heart disease. The critical difference between 'type-D' and Type C is that the 'negative' or dysphoric emotions of anger, anxiety, and depression are experienced, conscious, but suppressed by the type-D individual, while these emotions are usually unrecognized and thus subconscious and repressed by the Type C person. Thus, while both type-D and Type C have *phenotypically* similar non-expression of emotion, the '*genotypic*' or aetiological basis for this non-expression is different. Social inhibition, the tendency to inhibit the expression of emotions and behaviours in social interaction, is closely related to introversion. The negative affectivity or tendency to experience negative emotions in the type-D individual is theoretically related to neuroticism, and can be assessed adequately by measures of dysphoric mood, such as the trait form of Spielberger's State–Trait Anxiety Inventory. In contrast, Type C individuals are unable to report accurately on their repressed negative emotions because they are not aware of them. Thus, self-report scales, such as the Cortauld Emotional Control Scale, which assume that people are aware of the emotions that, subsequently, they are able to 'control', are not valid assessments of Type C (Temoshok, 2000b).

FUTURE PERSPECTIVES AND CONCLUSIONS

One of the main challenges in conducting research on the role of psychosocial factors in the progression of immunologically mediated diseases, such as cancer and HIV infection, is to devise methods to assess adaptive or maladaptive coping that have high predictive validity for biological processes and outcomes. Type C coping is particularly difficult to assess because the non-expressed, underlying negative emotions, particularly anger, are inaccessible to conscious recognition, and, thus, cannot be self-reported. This entry has described various methods of assessing the underlying emotion, as well as the manifest behavioural indicators of the Type C coping style. These assessment strategies, particularly the most recent and efficient method, the Vignette Similarity Rating Method, appear to be better able to 'capture' and encompass the complex, elusive, and multidimensional nature of the Type C coping pattern than traditional self-report scales. Ongoing and future research, using assessment methods that approximate the complex reality subsumed by this complex pattern, is aimed at understanding the mechanisms by which elements of the Type C pattern contribute to physiological and immunological processes that have implications for cancer and HIV progression.

U

UNOBTRUSIVE MEASURES

INTRODUCTION

All measures must be considered to be subject to error. We would have no way of knowing if, perchance, a measure turned out to be absolutely accurate. For example, the National Bureau of Standards has a ten gram weight (actually, because of manufacturing error just less than ten grams by about 400 micrograms, the weight of a grain or two of salt) (Freedman, Pisani & Purves, 1991). Despite the most careful weighing, done on a weekly basis, the values actually obtained for the standard weight vary by about 15 micrograms (one microgram is about the weight of a speck of dust) either way from the mean. Presumably, the mean of a long series of measures is the best *estimate* of the true weight of the standard, but there is no way of being sure of the true weight. Obviously, the way to deal with such errors, usually thought of as *random* errors, is to do the same measure several times. That is why careful carpenters measure their boards more than once before cutting them – especially if the wood is expensive. Random errors are associated with the concept of *reliability*, the expectation that if a measurement is performed twice under exactly the same conditions, very close agreement should be obtained if the measurement instrument and procedures for using it are dependable.

Another type of measurement error, though, is *bias*, i.e. consistent deviation from the 'true' value of the object or phenomenon of interest. For example, a recent news story recounted speculation that, in order to enhance the prospects of players for careers in professional American football, some collegiate coaches might have arranged the running tracks, on which the players' speed is tested, to be slightly downhill. If that is true, then the running speeds of players from some universities may be biased towards the fast end of the scale. If mothers are asked to estimate the intelligence (or good looks!) of their children, we might expect some bias to be evident, i.e. higher estimates than would be expected from other means of assessment. The bias is not reduced by replicating the measurement. Downhill is still downhill, and mother's love is constant.

The problem of bias has to be dealt with either by knowing the degree of bias so one can allow for it or by using multiple measures that do not share sources of error, i.e. bias (see Sechrest, 1979; Sechrest & Phillips, 1979). A football scout who knows that a player has been tested on a track with a downhill slant can 'allow' for that in interpreting reported running speed. We may expect that mothers will exaggerate a bit in describing their children's skills or other virtues and discount the glowing adjectives in the descriptions by some amount. But an even better way to deal with bias is to use other measures that are less biased, or not biased at all in the same way as the original measure. Of course, if a scout knows that a track has a downhill bias, that scout may simply retest

the athlete on a track known to be quite level and disregard the first, presumably biased, report. A scout might also use game films to arrive at a judgement of the speed of the player.

In social and behavioural sciences we usually have no absolute standard that can be applied, and we often should not assume that any one measure is less biased than another or unbiased altogether. The best solution is to use multiple measures of constructs and pick or devise those measures in such a way that they have minimally overlapping sources of error. A sports scout may not have any way of knowing that other running tracks are level, but if an athlete is tested on three different tracks, the average speed of those three runs is likely to be less biased (as well as having less random error) than any one of the runs. And, if all three tracks have a downhill slant, then maybe most tracks do, and the estimate of the athlete's speed is not biased with respect to estimates for other athletes.

PROBLEMS ASSOCIATED WITH SINGLE AND REACTIVE MEASURES

Social science measures are susceptible to many sources of bias, but a few of those sources of bias are particularly important because they are common and may involve relatively large degrees of bias. Different sources of bias are inherent in every measurement procedure. The biases can pose threats to the valid interpretation of a measure, in a manner akin to plausible rival hypotheses as threats to validity of experiments (Campbell & Stanley, 1963).

REACTIVE MEASUREMENT EFFECTS

A problem in measurement stems from the fact that the very act of measurement may produce a reaction on the part of the measured object that changes that object, whether temporarily or permanently. One cannot determine the tensile strength of a wire without breaking it, and one cannot determine whether a cake is as delicious as it looks without spoiling it to some degree. Asking to measure a person's height usually results in that person assuming a very erect posture that produces an estimate of height that is taller than their 'walking around' height. Similarly, giving a group of people a 'bigotry' scale is likely to result in an underestimate of the mean level of bigotry in the group, even if the scale is not explicitly labelled 'Bigotry Scale'. Some reactive measurement effects may be of limited duration or generalizability. The effect of bigotry measurement is unlikely to persist, but others may be long lasting, e.g. as when asking a person his or her opinion about something that results in reflection leading to crystallization of an opinion that may have previously been ephemeral.

Scientists and others involved in measurement in social sciences often attempt to reduce reactivity in various ways, including telling respondents that their responses will be confidential or even anonymous or that their responses will be used only for scientific purposes. Often such generic efforts to reduce reactivity are not enough, or at least not enough to be completely reassuring, in which case the response of the investigator may be to try to identify and employ a non-reactive, or at least less reactive, measure. Although all measures must be considered reactive to some degree, they are not all reactive to the same measurement issues or to the same degree. Other measures may be thought to be relatively low in reactivity because the data on which they are based were collected in spatially and temporally remote ways that should have freed them from contemporary biases. One example would be the use by historians of personal letters in order to diagnose the state of mind of the letter writer at some earlier period in his or her life.

The most obvious and attractive way of reducing reactivity is to carry out measurement activities under conditions that do not require the subject to know that he or she is being measured. Such measures have come to be known as *unobtrusive measures* (Webb et al., 1966). A young businesswoman might, for example, be invited out for lunch without knowing that she was actually being 'sized up' for a promotion. Or, computers in a school might be programmed to record sign-ons by individual students so as to provide a check on students' reports of computer use and study time. Measures may be unobtrusive because they are embedded in or derived from ongoing activities that do not make measurement a salient feature of the activity or because they are concealed in some way. The term *unobtrusive* has come to be used generically for non-reactive measures, but it would be better used to refer specifically to measures obtained without the

necessity that persons being measured be aware of the fact of being measured. It is for that reason that the original publication *Unobtrusive Measures: Nonreactive Measures in the Social Sciences* (Webb et al, 1966) was retitled *Non-reactive Measures in the Social Sciences* (Webb et al., 1981) in the revised version of the book. Some measures, e.g. many physiological measures, are not highly reactive (susceptible to bias) because they are not under voluntary control, other measures are not particularly reactive because the person being measured is mistaken about the purpose for which she is being measured, and still others because the measurement context is conducive to unbiased responding.

When people are aware of being measured, a frequent consequence is bias, even if the participant is cooperative and well intentioned. Persons being 'tested' often, very naturally, want to make a good impression, although in some specific instances, a person being measured may want to make what would ordinarily seem to be a bad impression, e.g. malingering. Persons being measured may adopt specialized roles that reflect their ideas about how they ought to behave, and those roles may not be characteristic of the persons when they are in other situations. Individuals will differ, of course, in the degree to which their characteristic responses are affected by knowledge of being measured. Bias may be limited in some instances because people believe their responses are completely appropriate. Criminals, for example, often believe that their behaviours are quite justified and therefore feel no need to disguise their statements about them.

Biases can be reduced with the implementation of multiple measures that do not share the same sources of bias. Unobtrusive measures are not free from their own sources of error, but they may not reflect the same type or degree of bias or reactivity as other measures. Unobtrusive measures, because they reflect different approaches to measurement, can often get around the limitations of reactive measures.

THE VARIETIES OF UNOBTRUSIVE MEASURES

Webb et al. (1966, 1981) provide an extensive review of unobtrusive or non-reactive measures in social science research and many fine examples can be found throughout the literature. Generally speaking, unobtrusive measures can be usefully categorized as follows:

1 *Simple observations*. Many interesting behaviours can be directly observed, often without the necessity of the observed actor being aware of the fact. Observations may be made of individuals and groups. Targets of observation may include objects and events as well as persons. For example, the nature of ceremonial events may be of great interest. Also included here are observations of physical location and clustering of people, expressive movements, language behaviour in the media or as overheard in public areas, the amount of time individuals spend gazing at public displays, or time sampling of observations to determine whether certain occurrences are linked temporally. A recent news story reported an observation that military dictators who begin to detect resistance and who desire to establish their legitimacy tend to abandon their military uniforms and don civilian attire, with recent appearances of Saddam Hussain of Iraq in regular business suits cited as an interesting example.
2 *Contrived observations*. Simple observation can be tedious as one may need to wait a long while for behaviour of interest to occur. Under such circumstances, researchers may contrive situations likely to produce relevant responses. The TV show 'You're on Candid Camera!' was based on responses of people to contrived situations. Social psychologists make extensive use of confederates in contrived situations in which the subject is unaware that he or she is a participant in an experiment. Also included in this category of contrived situations are the experiments in which unsuspecting individuals are deceived into doing things and studied in the process. Real estate companies are routinely tested for racial discriminatory practices by persons pretending to be clients. Bochner (1979) has made 'wrong number' phone calls and staged fake collapses on trains to assess individuals' helpfulness in common situations. These types of investigations can be classified as non-reactive or unobtrusive because the participants are unaware that

they are participating in an experiment. This lack of awareness implies that their reactions will be natural. Contrivances may include the use of hidden hardware such as audio- and videotapes.

3 *Physical traces*. These include both erosion and accretion measures. Measures of erosion include measurements of floor tile or carpet wear in front of various museum exhibits to determine their popularity or the wear and tear of library books to examine selective reader interest. Measures of accretion include indicators of inscriptions in public restrooms, the amount of debris left from a ticker-tape parade, or the number of cigarette packs that were thrown out with the trash in selected residential areas. Detectives regularly rely on physical traces of responses that they have never seen to solve crimes.

4 *Archives*. These include actuarial records. Materials supplied by the mass media, industrial and institutional records, sales records, and private written documents are archival records. Archival records are regularly used to track behaviours that might not otherwise be detected with reactive measures. Episodic personal and private records are in heavy use in hearings involving activities in the White House to check on the veracity of self-reports by those whose actions are in question.

It is important that unobtrusive measures not be regarded as substitutes for other kinds of reactive measures. That is the antithesis of the rationale behind unobtrusive measures. Unobtrusive measures are properly thought of as complementary to other measures such as questionnaires and interviews.

THE USES OF UNOBTRUSIVE MEASURES

The countering of bias in measurement is of focal concern in considering the usefulness of unobtrusive measures, but such measures may actually be adopted for other purposes. That is in part because an investigator may follow different strategies for dealing with bias: verification, adjustment, and avoidance. An investigator may believe that measures being used are not greatly biased, but he or she may also believe that caution requires sensitivity to possible bias. That investigator may elect to use one or more non-reactive measures in order to *probe* for bias in case it exists. For example, in a workplace study of attempts to induce exercise, a researcher may ask respondents how often they walk up stairs rather than take an elevator, and reports of workers might be regarded as generally unbiased. Nonetheless, the investigator might still elect to probe the accuracy of those reports by using occasional observers to determine whether the proportion of people climbing stairs is consistent with self-reports. If it should appear that workers tend to exaggerate their reported use of stairs, the investigator might change the questionnaire to try to elicit better data or abandon self-reports in favour of reliance on observers. A prudent investigator would at the very least be cautious in interpreting self-report data. Probing might not require large numbers of observations or observations of all subjects of interest. A second strategy is to collect sufficient data by alternative means to make it possible to estimate by how much the numbers obtained by a primary measure, likely to be a questionnaire, are off so that estimates can be appropriately discounted. Observational data might indicate that reported use of stairs is exaggerated by 25%, in which case the researcher might deflate his estimates of total physical activity by an appropriate amount. Obviously, unobtrusive measures may be used in conjunction with other measures to arrive at a summary assessment that is likely to be less biased than would have been the case for a single measure. If trainees in a programme claim to be spending ten hours per week in a computer laboratory, but actual counts of people working in the laboratory are not consistent with the claimed level of use, a researcher might adjust downward estimates of exposure to the exercises involved.

It is not always easy, however, to obtain unobtrusive measures that can be used directly and exactly in order to adjust for biases in other measures. One major problem is that more common measures such as questionnaires and unobtrusive or other non-reactive measures are not in the same metrics so that combining them is not easy. What would one do, for example, with questionnaire data indicating that people claim to eat four servings of vegetables every day and observational data indicating that many people fail to finish eating and discard portions of vegetables served to them? Such discrepant data

may lead one to question the accuracy of one set of data or the other, but the discrepancies may not translate easily into quantitative adjustments.

Which data should one trust? Certainly our inclination would likely be to distrust questionnaire and other self-report data. Campbell (1969) suggested as much in discussing the role of qualitative data in programme evaluation. Emily Dickinson once wrote the line in a poem 'I like a look of anguish because I know it's true'. That is likely to strike all of us as obviously true. Try to imagine the alternative statement 'I like a self-report of anguish because I know it's true'. And yet, there certainly must be times when self-reports are better assessments of underlying dispositions than overt behaviours. Think, for example, of the pressures towards conformity that lead people who may not be at all religious to bow their heads when other people pray, or the politeness that may prevail between politicians who dislike each other. The use of multiple and different measures cannot guarantee anything.

Under some circumstances, non-reactive measures may be available and be used alone. That may be because they are sometimes compelling, but also because they are sometimes inexpensive. In particular, archival records may be exploited, often at fairly low cost. If records are kept for reasons unrelated to any particular policy use, or at least for reasons unrelated to the purposes for which they are used in research, they may be of great value and characterized by very little bias. The identification by Dr. John Snow of a contaminated water supply as the cause of a cholera outbreak in London in the 1850s was facilitated by records kept of the location of individual cases of the infection, making it possible for Snow to map those cases onto alternative water systems (Freedman, 1991). Barthel and Holmes (1968) were able to use information in high school yearbooks to show that persons who later became schizophrenic had low levels of social activity before the onset of their illness.

ADVANTAGE AND LIMITATIONS OF UNOBTRUSIVE MEASURES

Advantages

Aside from the possibility of reducing bias in measurement, several other advantages are often associated with unobtrusive measures (Rathje, 1979; Babbie, 1989). Typically, unobtrusive measures require little, if any, effort on the part of persons being assessed, and often no physical contact with or even close proximity to participants is required. Unobtrusive measures tend to focus on behaviours and obviate the problems that may stem from inaccurate reporting on the part of respondents. Yet another advantage is that the employment of non-reactive measurement procedures is often relatively inexpensive, e.g. simple observations, physical traces, and archival records. They can be of great value in longitudinal studies.

Limitations

Unobtrusive measures, like all other measures, have limitations. In the first place, it is not always easy to identify unobtrusive measures. Unobtrusive methods are typically limited in certain areas that can be open to interrogation with more reactive methods such as interviews and questionnaires. Methods that utilize verbal communication, such as structured and unstructured interviews, have 'an ability to reach into all content areas' (Webb et al., 1966, 1981). Webb et al. (1981) provided a 'generative taxonomy' for non-reactive measures in order to facilitate thinking about them, but very often coming up with good ones is more an act of creative thinking than of straightforward science. No rules govern the process, and, hence, no limitations exist either. That means, however, that one cannot guarantee that an unobtrusive measure will be accepted by reviewers or readers of one's work. Unobtrusive measures are often novel and have no history of use in a field by means of which the case for them can be buttressed. Moreover, many unobtrusive measures do not readily fit the requirements of conventional psychometric analyses so that the usual indicators of difficulty level, variance, and so on are not available, and reliability cannot be directly computed. In the end, unobtrusive measures must have face validity, i.e. readers must see immediately and intuitively that they make sense. That is not always likely.

Unobtrusive measures may sometimes raise troubling ethical questions, for they may be obtained under conditions that at least appear to violate usual expectations about informed consent, confidentiality, and so on. Records may have been assembled with no expectation that they would ever be used for other than their original purposes, and even if confidentiality is protected at the public

level, some persons might feel that their personal confidence is breached when researchers gain access to their records. People may feel that even public behaviour is in some sense private if they have no expectation of being systematically observed. In fact, some courts have ruled that people riding in automobiles have expectations of privacy that should protect them against at least some types of observation. Ethical concerns may not rule out many unobtrusive measures, but at least they require careful consideration by researchers.

Neither are unobtrusive measures always inexpensive. Observers, for example, are expensive to train and support in the field, and unless they can produce information that is markedly better than what can be derived from questionnaires, they may not be affordable. Archives may be readily available, but the cost of mining them for usable data may be quite costly. Many other types of unobtrusive measures may be surprisingly expensive when one gets around actually to doing them. Questionnaires and interviews may be performed by mail, phone, or web sites, and the expenses associated with them, especially if multiple sites are involved, can make them a prohibitive favourite in the array of methods potentially available. As noted earlier, however, unobtrusive measures may still be useful at modest cost when used as probes into quality and bias of more traditional measures.

UTILITY

INTRODUCTION

Utility is always subjective and refers to the amount of personal or institutional satisfaction of an alternative. The personal satisfaction associated with the outcome of good food, a holiday trip or a sports car depends on taste, interests and needs. Institutional satisfaction associated with the

outcome of employment strategies or treatment selection predominantly depends on economic considerations. It is assumed that both individuals and institutions try to maximize their utility. Choosing alternatives according to their utility lies at the heart of all summative evaluation procedures.

PRESCRIPTIVE UTILITY THEORY

Utility Function

The measurement of utility has a long history in economics, starting with the measurement of preferences on an ordinal scale. Since von Neumann and Morgenstern (1947) developed the axiomatic foundation of utility, it can be measured on an interval scale. It is derived from personal preferences for either a sure thing or a gamble (Figure 1a). The decision maker is presented with a choice between obtaining either outcome o for sure or a gamble that returns with probability p a better outcome (o^*) and with complementary probability $(1-p)$ a worse outcome (o_*). The gamble is written as $[p\ o^*, (1-p)\ o_*]$ or simply $[p\ o^*, o_*]$ (the square denotes a decision, the circle a chance node).

With o^* and o_* as best and worst outcomes and all outcomes o_i in-between, the indifference probability π_i, where the decision maker is indifferent between the sure thing and the gamble, can be determined as $o_i \sim [\pi_i\ o^*, o^*]$. Pairs (o^*, π_i) of these indifferences constitute the utility function (Figure 2a). Above the function the gamble is preferred, below the function the sure thing is preferred. For outcomes with the following preference order $o^*\ \phi o_1 \phi o_2 \phi \ldots\ o_i \ldots \phi o_*$ the corresponding indifference probabilities with $1.0 = \pi^* > \pi_1 > \pi_2 > \cdots > \pi_i > \cdots > \pi_* = 0$ (as well as their linear transformations) are the utilities of the corresponding outcomes. Whenever the preference $o_i \phi o_j$ holds, the utility measurement of o_i exceeds o_j and $\pi_i > \pi_j$.

Axiomatic Foundation

The perceived utility of outcomes is the basis for expressing preferences. These preferences are analysed in order to measure true internal utilities. If the expressed preferences with respect to outcomes of alternatives (objects, commodities, events, strategies) and gambles meet the following six axioms, utility can be measured on an interval scale.

Ordering

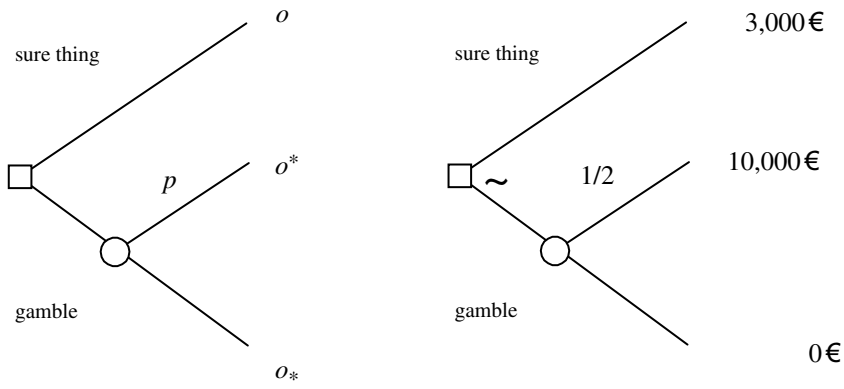
A decision maker should be able to compare outcomes and either prefer one to the other or be indifferent.

Transitivity

If one outcome is preferred to a second, and this second is preferred to a third, the first should also be preferred to the third.

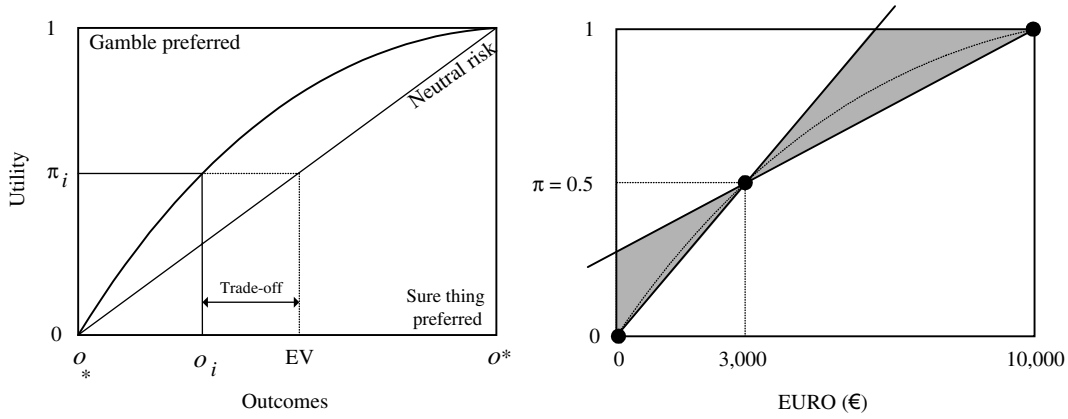
Dominance

A rational decision maker should never accept a dominated gamble whose best outcome matches



(a) The typical case (b) Finding the outcome $o_i \sim$ [½€ 10,000, €0]

Figure 1. The choice between a sure thing and a gamble.



(a) Risk averse utility function

(b) Constraints for utility functions arising from one elicited indifference

Figure 2. Utility functions.

the outcome of the sure thing and should always accept a gamble whose worst outcome matches the outcome of the sure thing.

Cancellation

Preferences for gambles must not depend on identical and equally probable outcomes.

Invariance

As long as the probabilities with which certain outcomes are obtained are the same, the form in which gambles are presented must not affect preferences.

Continuity

For a choice between a sure thing and a gamble there exists a probability p so that the sure thing is preferred and a probability p' so that the gamble is preferred.

Given the axioms, the utility of risky alternatives can be derived. Figure 3a illustrates a risky alternative with n possible outcomes of a strategy A where o_i is obtained with probability p_i. If the above axioms are met, A can be transformed into A' by replacing each outcome by its indifferent gamble taken from the utility function in Figure 2a. A' has only best and worst outcomes. A'' results when all best and all worst outcomes are combined and $\prod_A = \sum p_i \pi_i$ is the probability of obtaining the best outcome (Figures 3b and c). Since $A \sim A' \sim A''$, $\prod_A$ is the probability for the best outcome in gamble A'', the expected value (EV) of A' and the expected utility (EU) of A : $\mathrm{EU}(A) = \prod_A$. This helps: for two strategies (complex gambles) A and B it might be hard to decide whether $A \phi B$ or $B \phi A$ or $A \sim B$, but after utility measurement it is easy to establish whether $\prod_A > \prod_B$ or $\prod_B > \prod_A$ or $\prod_A = \prod_B$.

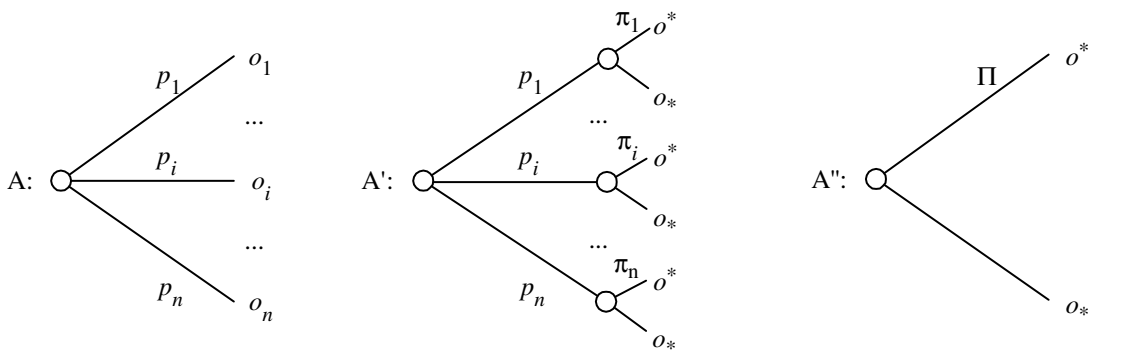
Four Steps of Measuring the Utility of Alternatives

Determine Outcome Ranges

Suppose a decision maker wants to evaluate strategies. In order to do so she has to determine the best and worst outcomes possible, which may be $E10{,}000$ at best and $E0$ at worst.

Specify Utility Functions

Determine the amount of Euro so that the decision maker is indifferent to obtain this amount for sure and the gamble of obtaining either $E1000$ or $E0$ with $\pi = 1/2$. Usually 5000 Euro for sure is preferred to the risky alternative with EV= $E5000$, and so is $E4000$. Assuming indifference holds for $E3000$, the utility function has to pass through the three points given in Figure 2b and is limited to the shaded area. Often the utility function is sufficiently well specified by eliciting just one well-chosen indifference point.



(a) Strategy *A* (b) Replacement of outcomes (c) Summarizing of branches

Figure 3. Three steps to determine the utility of a strategy *A*.

Find Out about the Alternatives

The decision maker has to establish the outcomes and their probabilities. This is a process of information seeking that may be assisted by experts.

Determine Probability Π

All outcomes are substituted with their indifferent gambles (taken from the utility function of step two, Figure 2a) in order to determine $EU(A) = \prod_A = \sum p_i \pi_i$.

The Concept of Risk

In many domains utility functions are concave, since the EV of the gamble exceeds the utility of the gamble. This is interpreted as decision makers being risk averse. Compared with the sure thing, a gamble is indifferent when its higher risk (bad) is traded-off by its higher EV (good). In other words, people and institutions tend to focus on avoiding bad outcomes at the expense of possibly missing good outcomes. Concavity is also a common result in value measurement. Here the concavity is interpreted as diminishing marginal value or satisfaction. The more there is of a common good, the less one additional unit will add to overall value.

Extensions

Subjective Probabilities

Savage (1954) broadened the concept of EU to subjective expected utility (SEU). Probabilities were no longer thought of as objective like relative frequencies. Subjective probabilities reflect degrees of belief, the extent to which a person believes certain outcomes will be obtained.

The Multiattribute Case

Often a single alternative may result in many outcomes on a variety of dimensions (attributes) (Keeney & Raiffa, 1976). For example, the institution's expected utility of a hiring decision may depend on the candidate's placement costs, salary, performance and soft skills. Ideally the utility of alternatives that vary on n dimensions can be derived from n unidimensional utilities according to SEU principles and the relative importance of the dimensions.

The Utility–Value Relation

The concepts of utility and value are similar but utility measurement is often restricted to the evaluation of alternatives involving risk whereas value assessment applies to cases of no risk. Compared with value assessment, the measurement of utility is more demanding (see Dyer & Sarin, 1979, for conditions of equivalence).

DESCRIPTIVE UTILITY THEORIES

Since empirical findings do not always support the normative and prescriptive theories outlined previously, descriptive theories of utilities have

been proposed that better describe decision makers' actual behaviour.

Among such theories, prospect theory by Kahneman and Tversky (1979) is known best. It proposes that the utility of outcomes are evaluated in comparison to a reference point (status quo) as gains or losses. The utility function for gains is concave, for losses convex, and steeper for losses than for gains. Prospect theory explains why decision makers deviate from SEU predictions. Prominent examples are risk seeking behaviour in the domain of losses and risk avoiding behaviour in the domain of gains. Other theories are disappointment theory where utilities partly depend on a priori expectations, and regret theory, where utilities depend on the loss with respect to the a posteriori best alternative.

APPLICATION TO PSYCHOLOGICAL ASSESSMENT

Cronbach and Gleser (1965) have introduced the utility concept to psychological assessment. The utility of classification strategies depend on actual probabilities of hits, misses, false alarms and correct rejections multiplied by the associated costs and benefits.

FUTURE PERSPECTIVES AND CONCLUSIONS

Prescriptive utility theory can help to identify promising alternatives. Descriptive utility theories explain and predict actual decision behaviour and help to protect against common traps. Taking both viewpoints into account will improve decisions, ensuring higher utilities and better lives for individual decision makers as well as institutions.

VALIDITY (GENERAL)

INTRODUCTION

Tests and other forms of assessment are designed to provide information that will be useful for some purpose. The degree to which the information provided by a test score is useful, appropriate, and accurate is described by the psychometric concept *validity*. Validity is the extent to which the inferences (interpretations) derived from test scores are justifiable from both scientific and equity perspectives. For decisions based on test scores to be valid, the use of a test for a particular purpose must be supported by theory and empirical evidence, and biases in the measurement process must be ruled out.

Validity is not an intrinsic property of a test. As many psychometricians have pointed out (e.g. Cronbach, 1971; Messick, 1989; Shepard, 1993), in judging the worth of a test, it is the inferences derived from the test scores that must be validated, not the test itself. Therefore, the specific purpose(s) for which test scores are being used must be considered when evaluating validity. For example, a test may be useful for one purpose, such as patient diagnosis, but not for another, such as evaluating the treatment of patients.

Contemporary definitions of validity in testing borrow largely from Messick (1989) who stated 'validity is an integrated evaluative judgement of the degree to which empirical evidence and theoretical rationales support the *adequacy* and *appropriateness* of *inferences* and *actions* based on test scores or other modes of assessment' (p. 13). From this definition, it is clear that validity is not something that can be established by a single study and that tests cannot be labelled 'valid' or 'invalid'. Given that (a) validity is the most important consideration in evaluating the use of a test for a particular purpose, and (b) such utility can never be unequivocally established, establishing that a test is appropriate for a particular purpose is an arduous task. In the remainder of this entry, specific forms of evidence for validity as well as some validation frameworks will be discussed. Before describing these concepts and practices, the following facts about validity in testing should be clear: (a) tests must be evaluated with respect to a particular purpose, (b) what needs to be validated are the inferences derived from test scores, not the test itself, (c) evaluating inferences made from test scores involves several different types of qualitative and quantitative evidence, and (d) evaluating the validity of inferences derived from test scores is not a one-time event; it is a continuous process. In addition, it should be noted that although test developers must provide evidence to support the validity of the interpretations that are likely to be made from test scores, ultimately it is the responsibility of the users of a test to evaluate this evidence to ensure the test is appropriate for the purpose(s) for which it is being used.

TEST VALIDATION

To make the task of validating inferences derived from test scores both scientifically sound and manageable, Kane (1992) proposed an 'argument-based approach to validity'. In this approach, the validator builds an argument based on empirical evidence to support the use of a test for a particular purpose. Although this validation framework acknowledges that validity can never be established absolutely, it requires evidence that (a) the test measures what it claims to measure, (b) the test scores display adequate reliability, and (c) test scores display relationships with other variables in a manner congruent with its predicted properties. Kane's practical perspective is congruent with the *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA], American Psychological Association [APA], & National Council on Measurement in Education [NCME], 1999), which provide detailed guidance regarding the types of evidence that should be brought forward to support the use of a test for a particular purpose. For example, the *Standards* state:

> A sound validity argument integrates various strands of evidence into a coherent account of the degree to which existing evidence and theory support the intended interpretation of test scores for specific uses ... Ultimately, the validity of an intended interpretation ... relies on all the available evidence relevant to the technical quality of a testing system. This includes evidence of careful test construction; adequate score reliability; appropriate test administration and scoring; accurate score scaling, equating, and standard setting; and careful attention to fairness for all examinees ... (p. 17)

GATHERING VALIDITY EVIDENCE

To build a validity argument for a test, there are several types of evidence that can be brought forward. Traditionally, the major forms of validity evidence are *content validity*, *criterion-related validity*, and *construct validity*. Each of these terms is described more completely in separate entries of this encyclopedia. Briefly, content validity evidence involves gathering data from content experts regarding the degree to which the behaviours sampled on the test represent the behaviours the test is designed to measure. Criterion-related validity evidence involves evaluating correlations among test scores and other variables related to the construct measured. Predictive and concurrent validity are special cases of criterion-related validity that involve correlating test scores with future or current criterion performance. Construct validity involves gathering data that show test scores are indicative of the construct measured. Many test theorists (e.g. AERA et al., 1999; Messick, 1989) consider content and criterion validity to be subcomponents of construct validity because such evidence assists in evaluating test-construct congruence.

Regardless of the types of data gathered to evaluate validity and the labels we apply to the validity evidence, two factors guiding test validation are evaluating construct representation and construct-irrelevant variance. Evaluating construct representation means inquiring whether all important aspects of the construct are measured by a test. Evaluating construct-irrelevant variance involves ruling out extraneous behaviours measured by a test. An example of construct-irrelevant variance is 'method bias', where test scores are contaminated by the mode of assessment. Campbell and Fiske (1959) proposed a *multitrait–multimethod* framework for studying construct representation (e.g. convergent validity) and construct-irrelevant variance due to method bias (discriminant validity).

Contemporary test validation is a complex endeavour involving a variety of studies aimed toward demonstrating that a test is measuring what it claims to measure and that potential sources of invalidity are ruled out. Such studies include (1) dimensionality analyses to ensure the structure of item response data is congruent with the intended test structure, (2) differential item functioning analyses to rule out item bias, (3) content validity studies to ensure the relevance and appropriateness of test content, (4) criterion-related validity studies to evaluate hypothesized relationships among test scores and external variables, and (5) surveys of invested stakeholders such as test-takers and test administrators. Relatively recent additions to test validation are studies focusing on social considerations associated with a testing programme including unintended consequences such as narrowing the

curriculum to improve students' scores on educational tests. It should also be noted that evidence of adequate test score reliability is a prerequisite for supporting the use of a test for a particular purpose since inconsistency in measurement due to content sampling, task specificity, ambiguous scoring rubrics, the passage of time, and other factors adds construct-irrelevant variance (i.e. error variance) to test scores.

FUTURE PERSPECTIVES

Validity was, is, and always will be the ultimate criterion for evaluating the worth and defensibility of a particular test for a particular purpose. Validity theory will evolve to address issues such as distinguishing between 'constructs' and 'content domains' as well as determining the degree to which the social consequences of a testing programme should be considered when evaluating a test. Test validation activities will evolve as statistical procedures evolve and as we expand the types of data we gather to evaluate tests. Recent statistical advances in test validation include applications of structural equation modelling to construct validity (e.g. Pitoniak, Sireci & Luecht, 2002; Reise, Widaman & Pugh, 1993) and applications of multidimensional scaling to content validity (Sireci, 1998a). Examples of newer types of data gathered to evaluate validity include item response (reaction time) data (e.g. van der Linden, Scrams & Schnipke 1999) and the coding of item features to gauge the specific cognitive processes measured by test items (e.g. Sheehan, 1997; Tatsuoka, 1993). Another relatively recent development that has the potential to affect validity is computer-based assessment. It is likely that computer-based assessment will allow us to measure psychological constructs that are not measurable in the more traditional paper-and-pencil format (Huff & Sireci, 2001).

CONCLUSIONS

Given that validity is the ultimate criterion for judging the worth of a test for a particular purpose, it is not surprising that theories of test validity and methods for test validation are as old as the process of testing itself (Sireci, 1998b). Validity studies are critically important for maintaining the scientific credibility of educational and psychological assessment. As we seek to learn more about the validity of a test for a particular purpose, we gradually improve our ability to measure psychological constructs, which remain some of the most intractable constructs of modern science. Psychological assessment is at the heart of scientific psychology. Validity is the heart of psychological assessment.

VALIDITY: CONSTRUCT

INTRODUCTION

Construct validity is recognized as the fundamental and all-inclusive validity concept insofar as it specifies what categories, traits or factors a test measures (Anastasi & Urbina, 1997; Cronbach, 1988; Messick, 1989). Professional standards addressing validity were first codified in the 1954 *Technical Recommendations for Psychological Tests and Diagnostic Techniques* (American Psychological Association, 1954). At that time, four separate and distinct types of validity were specified: construct, content, predictive, and concurrent. The former two types of validity were subsumed within criterion-related validity and the resulting three types of validity were referred to as the holy trinity (Guion, 1980). Each type of validity was largely associated with a specific use of tests as separate and exclusive methods of validation became entrenched by different camps of test developers and users (Shepard, 1993). In employment, many developers of personnel or certification tests argued that content validation approaches were sufficient, while developers of biodata instruments and other selection instruments relied exclusively on criterion-related strategies. When viewed as separate and exclusive types of validity, construct validity was considered appropriate when making inferences about traits that were not directly observable such as intelligence or conscientiousness.

A construct is a concept or characteristic an assessment attempts to measure. Latent anxiety, emotional stability, managerial performance, and conscientiousness are constructs typically discussed in the psychological literature. However, ability to design a web-page, mathematical reasoning ability, oral communications, and ability to trouble-shoot technical problems with equipment are also examples of constructs. A detailed description of the construct and an articulated definition which delineates the knowledge, skills, abilities, processes, and characteristics to be assessed should accompany descriptions of attributes that are measured.

CONSTRUCTS

Construct validity has emphasized the role of educational and psychological theory in test construction and focused attention on the need to develop hypotheses that can be supported or disconfirmed through validation studies. Cronbach and Meehl (1955) express the need to make one's theoretical ideas and hypotheses as explicit as possible and propose the concept of a 'nomological net'. Simply stated, they hypothesized a construct with various connections to other behaviours and measures and noted that validation studies would provide evidence of which relationships exist among observable measures as well as instances when a plausible rival hypothesis exists. Campbell and Fiske (1959) offered a conceptual and empirical framework for construct validation. Conceptually, any measure of a given construct have stronger relationships with other measures of the same construct while having weaker relationships with measures of different constructs. The former process is referred to as convergent

validation evidence and the latter process is referred to as discriminate validation evidence. Guion (1998) has suggested comparing the weight of evidence supporting specific inferences from test scores to the weight of evidence opposing such inferences. Empirically, such evidence would often take the form of correlations between similar and different constructs using similar and different methods. Methods may include the type of assessment items used (e.g. multiple-choice, constructed-response) or the actual measurement tool employed (e.g. structured interview, observations, oral presentation, portfolio, test).

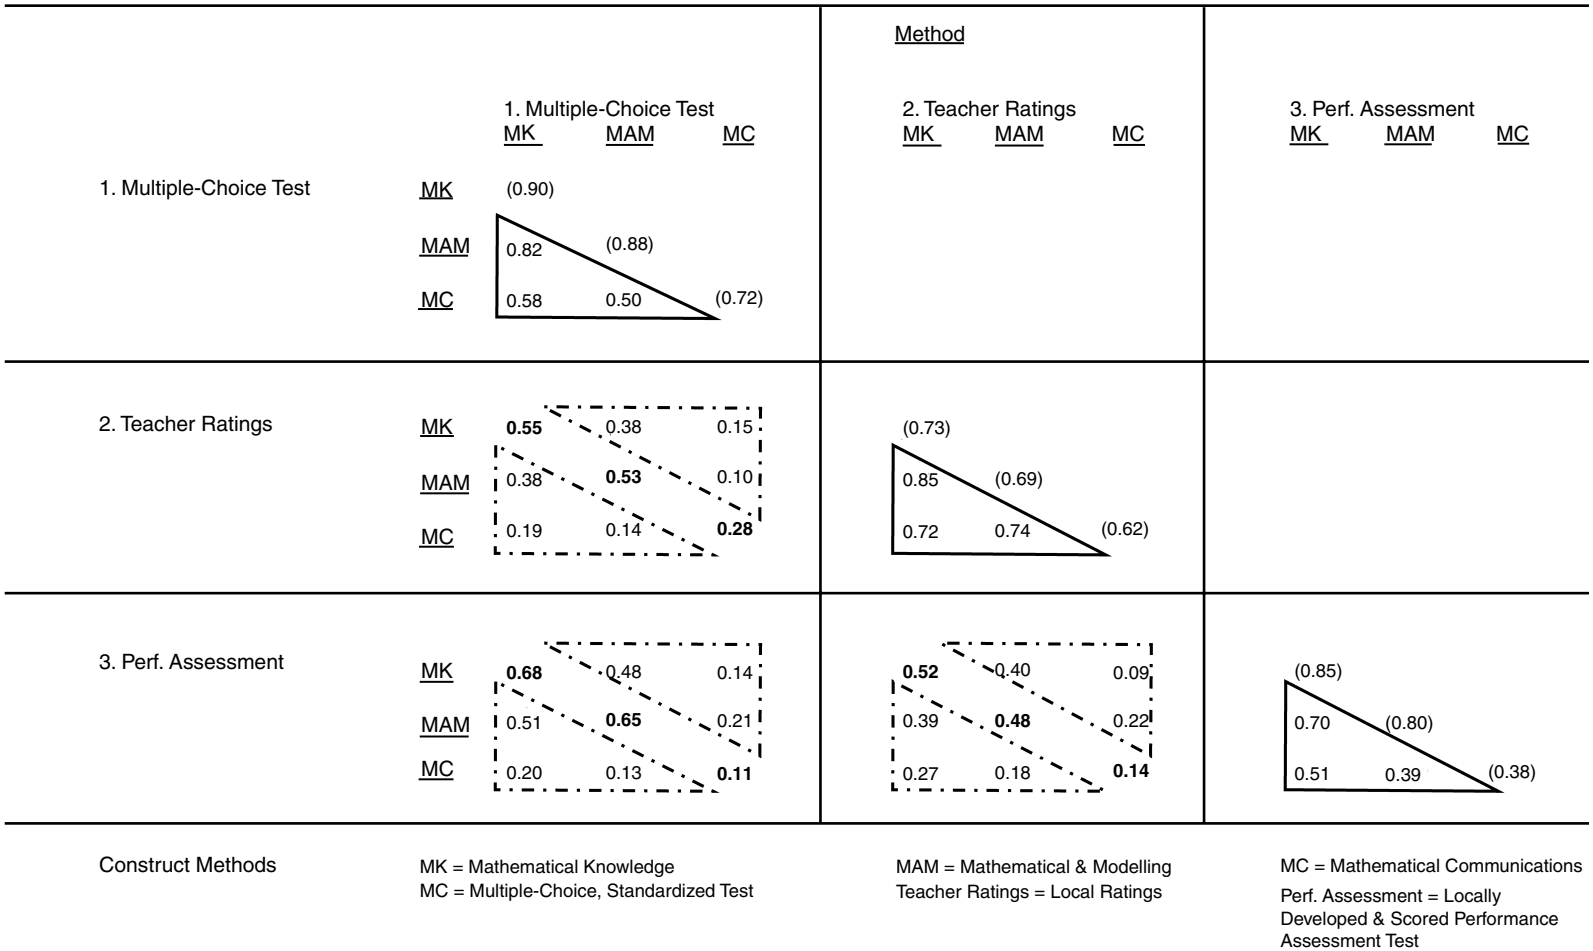
CONSTRUCT EVIDENCE: CONVERGENT AND DISCRIMINATE EVIDENCE

Table 1 provides a hypothetical example (based on an example provided by Campbell and Fiske, 1959: 82) where three constructs are measured by three different methods. This multitrait–multirater matrix is one method used to determine the convergent and discriminate evidence central to findings of construct validity. In this example we examine three different traits or constructs relating to quantitative reasoning, (a) mathematical knowledge, (b) mathematical applications and modelling, and (c) mathematical communication, with three measures: (1) a standardized multiple-choice test, (2) teacher ratings, and (3) a performance assessment. The solid triangles illustrate the correlations of different constructs measured by the same method and the dotted triangles illustrate the correlations of the same construct measured by different methods. The principal diagonal is the reliability of each method and construct (in parentheses), and the three short diagonals illustrate the overall relationship between different methods or measures of the same construct (in bold). These latter correlations would be considered the validity coefficients because they illustrate the relationship between the different measures of the same construct; however, all the data in such a matrix can provide confirming or discriminate evidence relating to validation of the measures and constructs.

Evaluation of the correlational matrix should proceed from a logical construct theory. 'In effect, discriminant validity is a necessary test of construct validity, even a stronger test in this sense than is convergent validity because it implies a challenge from a plausible rival hypothesis' (Angoff, 1988: 27). In the above example, the validity correlations (in bold) should be higher than correlations between different constructs (both when the same method is used as well as when different methods are used). For example, the validity coefficient between mathematical knowledge measured by the standardized test and teacher ratings should be higher than the correlation between mathematical knowledge and applications and modelling measured by either the test or the teacher's ratings. The data in Table 1 do not provide a clear and unambiguous support for construct validity through the convergent or divergent evidence. The data illustrate a moderately strong relationship between different constructs within the same method, suggesting some degree of method-specific variance may confound these measures. That is, it appears that teacher ratings of all three constructs are highly related, just as test scores of all constructs are highly related. In most instances, the relationship between different constructs measured with the same method exceeds the intra-construct correlations, resulting in a lack of discriminant validity. One possible reason for this may be that quantitative reasoning is a unidimensional construct; while another possibility is that the methods used to measure these constructs were not sensitive enough to detect differences. In addition, the performance measure of mathematical communications has a relatively low internal reliability, resulting in lower validity coefficients than intercorrelations with other constructs.

Personality traits or specific skills and abilities are more commonly employed in psychological and industrial-organizational contexts. Discriminant and convergent evidence may be established when test and non-test measures of the same construct are highly related. In employment settings, correlations between supervisory ratings, performance assessments, and cognitive ability tests are often conducted to provide such evidence (e.g. physical strength, and endurance). All physical ability testing are, to some degree, measures of constructs, and job performance criterion ratings of incumbents' effectiveness in lifting, pulling, or carrying should be related to performance on selection measures corresponding to this construct (Hogan & Quigley, 1996). Many occupations such as firefighter, police officer, and some military occupations will

Table 1. Hypothetical example of the multitrait–multirate method



require minimum physical abilities that are related to job performance. Evidence establishing the relationship between the actual physical ability measures and job criterion ratings can aid in establishing convergent validation evidence. Similarly, psychological literature contains many studies relating the strength of relationships among subtests of well established personality or intelligence tests, as well as with other measures of the same constructs. For example, many studies have been conducted examining the 'big five' personality dimensions (agreeableness, conscientiousness, emotional stability, extroversion, and openness to experience) (Barrick & Mount, 1991). Such convergent evidence has also been widely used in cognitive ability testing and other areas, specific abilities and skills have been identified and reported separately (Jaegar, Linn & Tesh, 1989).

CONSTRUCT-IRRELEVANCE AND INTERNAL STRUCTURES OF AN ASSESSMENT

Convergent and discriminant evidence alone are not adequate in establishing evidence to support the validity of inferences made from assessment scores or results. Messick (1989) noted that construct irrelevant sources of variance also present a challenge. Such irrelevant variance can be introduced when an employment test uses language that is at a much higher reading level than required of a job, when a popular clinical psychological personality test is used for promotion or retention without adequate evidence of job relatedness or when a mathematics achievement test uses complex constructive-response tasks that require proficiency in English language that may overshadow the mathematics construct it is intended to measure.

The 1999 *Standards for Educational and Psychological Testing* (AERA, APA & NCME, 1999) state that validation begins with 'an explicit statement of the proposed interpretation of test scores along with a rationale for the relevance of the interpretation to the proposed use. The proposed interpretation refers to the construct or concepts the test is intended to measure' (AERA et al., 1999: 9). They describe five sources of evidence that can contribute to a validation argument and be used in evaluating a proposed interpretation of test scores for a particular use: (1) content, (2) relationships between test scores and other variables, (3) internal structure of the test, (4) response processes, and (5) consequences of testing. Validity is a unitary concept and such distinctions refer to various sources of evidence rather than distinct types of validity. However, several of these sources of evidence are more directly related to the traditional view of construct validation.

Construct validity theory has focused attention on the role of psychological theory in test construction and the need to develop hypotheses that can be proved or disproved as validation evidence gradually accumulated over time (Anastasi & Urbina, 1997). Evidence of relationships between test scores and other variables includes two distinct types of evidence: (a) empirical evidence relating a predictor to a criterion, and (b) relationships between two measures of the same construct. This latter form of evidence encompasses both convergent and discriminant evidence and has been discussed above.

Evidence based on the internal structure of the test may examine the relationship among items or tasks and how test scores may relate to specific aspects of a construct.

A test developer initially sets out to measure a trait or skill (i.e. construct) by developing tasks or writing items that would apparently relate to this trait or skill. Correlational analyses are typically used to determine the relationship among items on a test and between items and total test score. High intercorrelations among items or tasks provide evidence that items measure a similar construct. Correlational matrices help to show such relationships among items or variables.

Exploratory factor analysis is based on correlational analyses and is often used when a test developer is uncertain about the relationship of items or tasks to one of more constructs or when a researcher wishes to identify common constructs or traits across a variety of measures. The primary purpose of exploratory factor analysis is to simplify the description of the data by reducing the number of variables or dimensions. Factor analysis reduces variables (items, tasks, dimensions) by finding clusters of highly correlated variables which are minimally correlated with other clusters of variables. For example, when a test or inventory is intended to measure several facets of a construct (e.g. communication may have receptive, expressive and written communication

facets) evidence of item heterogeneity may support inferences concerning the validity of subcomponents of the test. Evidence concerning whether certain tasks or items function differently for different groups may also provide evidence relating to the internal structure of the test. Factor analysis and measures of internal consistency are examples of specific forms of statistical analyses commonly used to accumulate evidence of the internal structure of a test or other measure. Related methods such as cluster analysis, linkage analysis, and canonical correlations are similarly based on the assumption that similar patterns of correlations among items or tasks provide evidence of a single construct (Guion, 1998). Multidimensional scaling graphically plots pairs of variables based on their relationship, using graphically distance to simplify data on items, tasks, or variables.

When there is a strong hypothesis about constructs and how they are measured, confirmatory factor analysis is preferred. With this approach, the researcher specifies the expected factors and the relationship among different measures (e.g. items, tasks, tests) and the fit of data to the a priori model confirms or disconfirms the model. In the case of factor analysis, the concern is with the structure of individual differences with respect to a specified domain of variables (Torgerson, 1983). Similarly, structural equation modelling and other methods of causal modelling have provided important advances in validation because they can provide evidence concerning the causal relationships between constructs and the paths whereby a predictor affects criterion performance (Schmidt, Hunter & Outerbridge, 1986).

FUTURE PERSPECTIVES AND CONCLUSIONS

Construct comes from construe, and construct validity evidence is a method of construing or organizing data to explain test scores, what they measure and what they mean. With the release of the most recent edition of the *Standards for Educational and Psychological Testing* (AERA, APA & NCME, 1999), construct validity has transformed from one of the trinitarian methods of obtaining validation evidence to the fundamental and all-inclusive validity concept. Comparisons of the relationship between tests and external measures of a construct can provide convergent and discriminate evidence. Analysis of the internal structure of a test and its scores or subcomponents can provide construct evidence for the validity of test scores and their interpretation. Correlations among items and measures provide the simplest form of such internal evidence, while factor analysis, cluster analysis and multidimensional scaling are more sophisticated approaches to examine the relationship among items and measures or to evaluate an a priori model. Structural equation modelling and multidimensional scaling are increasingly used to examine the relationship among substantive and methodological variables that influence the level of construct evidence. However, given the new testing standards, all forms of evidence, including content and criterion-related, will be subsumed as construct evidence. The application of this new and emerging concept of test validity over the next decade is likely to change our operational approaches and overall views of validation approaches.

VALIDITY: CONTENT

INTRODUCTION

Content validity is the degree to which an assessment represents the content domain it is designed to measure. When an assessment is judged to have high content validity, the content of the assessment is considered to be congruent with the testing purpose and with prevailing notions of the subject matter tested.

Evaluating content validity is an important part of validating the use of a test for a particular purpose, especially when the test is educational in nature, such as when it is desired to measure a person's knowledge of specific subject matter (e.g. achievement and licensure tests). Although the process of test validation is dynamic and a test is never 'validated' per se, in many cases, evidence of content validity is a fundamental component for defending the use of a test for a particular purpose.

Content validity is a notion with which lay people can easily identify and understand. For example, parents and teachers expect items on an elementary mathematics test to be consistent with the elementary mathematics curriculum taught in the schools. Similarly, the general public expects items on a test used to license public accountants to be congruent with the tasks public accountants confront when performing their duties. The evaluation of test content vis-à-vis testing purpose is a natural first step in judging the utility and quality of an assessment. Thus, it is not surprising that the term content validity was included in the earliest efforts to develop standards for test development and evaluation (i.e. American Psychological Association [APA], 1952).

ASPECTS OF CONTENT VALIDITY

There are at least two aspects of content validity: *domain definition* and *domain representation*. Domain definition refers to the operational definition of the content domain tested.[1] This operational definition is often accomplished by providing descriptions of the content areas and cognitive abilities the test is designed to measure. To adequately define the content domain, several different sources may be used, depending on the purpose of the assessment. These sources include basal textbooks and curriculum objectives for educational tests, job analysis results for employment or licensure tests, and theories of mental abilities and functioning for aptitude tests.

Content domains are often formally defined using test specifications. These specifications,

which are typically in the form of a two-by-two grid listing the content areas along one dimension and the cognitive levels along another dimension, specify the relative weights that are assigned to each of these facets of the content domain. Most technical manuals for tests include these descriptions and specifications. By reviewing the descriptions of the content areas and cognitive levels measured on an assessment, along with the percentages of items that are designed to measure each area/level, one can get a good sense of how the test developers conceptualized the content domain. An understanding of this conceptualization is critical for evaluating the appropriateness of a test for a particular purpose.

Domain representation refers to the degree to which an assessment represents and adequately measures all facets of the content domain tested. The degree to which the content of an assessment spans the entire domain (domain coverage) is one important aspect of domain representation. Another important aspect is domain relevance, which addresses the relevance of each test item to the domain tested. By evaluating domain coverage it can be ascertained whether the entire content domain is being measured, as well as whether critical facets of the content domain are underemphasized. By evaluating domain relevance, the adequacy and importance of each test item for measuring the content domain can be scrutinized. In addition, problems of content-irrelevance can be identified. The current version of the *Standards for Educational and Psychological Testing* (AERA, APA & NCME, 1999) underscores the need for providing evidence of domain representation:

> Test developers should provide evidence of the extent to which the test items and scoring criteria represent the desired domain. This affords a basis to help determine whether performance on the test can be generalized to the domain that is being assessed. (p. 45)

CONTENT VALIDITY STUDIES

Most, but not all, studies of content validity require content experts to review test specifications and items according to specific evaluation criteria. Thus, a content validity study typically involves gathering data on test quality from professionals with expertise in the content domain tested. Content validity studies differ according to the specific tasks presented to the experts and the types of data gathered. One example of a content validity study is to give content experts the test specifications and the test items and ask them to match each item to the content area, educational objective, or cognitive level that it measures. In another type of study, the experts are asked to rate the relevance of each test item to each of the areas, objectives, or levels measured by the test. Extensive discussions of such studies are provided by Crocker, Miller, and Franks (1989), Hambleton (1984), and Sireci (1998a). The data gathered from these studies can be summarized using simple descriptive statistics, such as the proportion of experts who classified an item as it was listed in the test specifications or the mean relevance ratings for an item across all areas tested. A 'content validity index' can be computed for a test by averaging these statistics over all test items. More sophisticated procedures for analysing these data have been proposed by Aiken (1980) and Crocker et al. (1989).

Sireci and Geisinger (1992, 1995) introduced a newer method for evaluating test content that requires content experts to make judgements regarding the similarity of the content measured by pairs of test items. These similarity data are analysed using multidimensional scaling to determine if the structure of the experts' similarity ratings is congruent with the structure outlined in the test specifications.

Other studies that also provide evidence of content validity are job analyses (referred to as practice analyses for licensure testing) and sensitivity reviews. As mentioned earlier, job analyses are often conducted to operationally define the content domain to be tested. Data gathered from such analyses can be used to derive weights (e.g. proportions of test items) for specific content areas as well as to defend the specific areas tested. In a sensitivity review, experts in cultural diversity inspect test items to check whether content bias may be present (Sireci & Mullane, 1994). Such studies can identify items that introduce construct-irrelevant variance, such as differential familiarity of item context across cultures or sexes.

FUTURE PERSPECTIVES

The term 'content validity' was widely used by the psychometric community until the middle 1970s when Messick and others proposed a unitary conceptualization of validity centred on construct validity (e.g. Guion, 1977; Messick, 1975; Messick,

1989). Proponents of this unitary conceptualization of validity suggest using terms such as 'content representativeness' in place of content validity because content validity focuses on the test itself rather than on inferences derived from test scores. This perspective was incorporated into the current version of the *Standards for Educational and Psychological Testing* (AERA, APA & NCME, 1999), which uses the phrase 'evidence based on test content' in place of content validity. However, many test specialists believe content validity is a legitimate term since evaluating test content is a critical aspect of defending the legitimacy of inferences derived from test scores (e.g. Sireci, 1998a, 1998b). Regardless of debates over terminology, the fundamental qualities described by content validity (i.e. domain definition and representation) will remain important criteria for evaluating assessments for as long as assessments are used to make inferences regarding individuals' knowledge, skills, and abilities.

CONCLUSIONS

Historically, as the stakes associated with psychological assessments increased, the methods used to evaluate the assessments also increased. The concept of content validity and the process of content validation emerged to address the limitations of purely statistical (correlational) approaches to test validation (Sireci, 1998b). Clearly, for interpretations of assessment results to be valid (a) the content of a test needs to be congruent with the testing purpose, and (b) the content areas to which an assessment is targeted need to be adequately represented. Thus, content validity is a prerequisite for valid interpretation of many educational and psychological assessments. In evaluating content validity, the adequacy of the domain definition, the degree to which the test represents the content domain, and the relevance of the test items to the domain should be studied.

Note

1 The terms 'content domain' and 'construct' are sometimes used interchangeably. As the 1985 version of the *Standards* stated 'there is often no sharp distinction between test content and test construct' (American Educational Research Association [AERA] APA & National Council on Measurement in Education [NCME], 1985: 11).

VALIDITY (GENERAL), CRITERION-REFERENCED TESTING: METHODS AND PROCEDURES, VALIDITY: CRITERION-RELATED, VALIDITY: CONSTRUCT, THEORETICAL PERSPECTIVE: PSYCHOMETRICS CLASSICAL TEST THEORY, STANDARD FOR EDUCATIONAL AND PSYCHOLOGICAL TESTING

VALIDITY: CRITERION-RELATED

INTRODUCTION

Criterion-related validity involves verification that a test score is systematically related to an external variable. The current view on validity in the 1999 *Standards for Educational and Psychological Testing* (AERA, 1999) stresses the unity of psychological theory, evidence, and consequences in supporting the validity of a test used for a particular purpose. Seldom is there a direct use of a test for decision-making, however, that cannot be cast into a framework in which criterion-related validity applies.

For many types of educational and psychological tests, the accurate prediction of a criterion of interest is the primary virtue of the test score. Investigations of criterion-related validity justify using a test for employee selection, college admission, or clinical diagnosis when they demonstrate a correlation between scores on the predictor test and a relevant criterion of success or correct classification and treatment. However, many situations arise in test use in which the relevance of criterion-related validity is less apparent. When an achievement test is used in a high-stakes environment to identify students unprepared for high school, or when a licensure exam is used to deny a teaching credential, the justification for test use is typically based on the relevance of test content to high school coursework or teaching practice. In these settings, poor test performance presumably indicates likely failure in the criterion situation. The difficulty of distinguishing the importance of test content, the statistical relationship of a test to a criterion, and the construct interpretations of both characterizes the unitary view of validity in the 1999 *Standards*. Thus, the approach to validity described here should be understood in the broader context of current professional standards on validity as a unitary concept.

Studies of criterion-related validity represent one area of test validation research in which quantitative evidence is used to endorse or challenge the legitimacy of actual test use. The combined roles of theory and judgement are critical in forming validity arguments. Yet their influence in actual test use (e.g. individualizing instruction for students in an elementary school) is documented directly in the relation of the test score to an external variable closely matching the desired outcome (e.g. higher achievement from instruction matched to students' developmental level). In this sense, criterion-related validity has been described as an 'external aspect of construct validity' (Heubert & Hauser, 1998). This is precisely why criterion-related validity is so important when tests are used to make high-stakes decisions.

THE CRITERION PROBLEM

Establishing the criterion-related validity of a test presumes the availability of a measurable outcome of interest. A test designed to predict success in a job training programme requires a reliable, valid measure of that success to establish criterion-related validity. This measure could be a supervisor's rating of job performance, a direct measure of productivity such as sales transactions or units assembled, an evaluation of a work sample, or simply the number of days present on the job. Actual measures of criterion performance frequently receive less attention than the tests designed to predict them, rendering the criterion itself the weak link in the argument supporting validity of the predictor.

Although the criterion problem has received much attention in the literature, particularly in personnel and military psychology criterion measurement remains plagued by problems of inadequate construct definitions and poor instrumentation. A supervisor's rating of an employee's performance can be influenced by a host of factors irrelevant to the construct of interest, such as a response set that homogenizes staff ratings to prevent employee tensions or some other halo effect based on employment history.

A quantitative measure of success in school, such as grade-point average, is influenced by course-taking patterns, varying standards, and lack of agreement within an institution about the meaning of grades. The measured outcome of a response to treatment may be a subsequent clinical assessment influenced by the biases of an examiner. In each of these examples, inadequate criterion measurement confounds the interpretation of findings from a criterion-related validity study.

PERTINENT DATA AND LIMITATIONS

In most settings, criterion predictions are based on a linear regression model of the form

$$Y_i = \beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3} + \cdots + \beta_p X_{ip} + \epsilon_i, \quad (1)$$

where Y_i is the score of person i on the criterion, X_{ij} is the score of individual i on predictor j, β_j is the raw-score regression weight of predictor j, β_0 is the intercept, and ε_i is the error of prediction. The X_{ij}'s may be, for example, subscores on a test of general cognitive ability and Y_i an achievement composite. Estimates of the regression weights and intercept would come from a random sample of reasonable size given the number of predictors in the model. The squared multiple correlation between Y and the X_j's describes the strength of the linear relationship in equation (1), and the standard deviation of the ε_i's indicates the average magnitude of a prediction error. Cross-validation techniques are sometimes used to evaluate the stability of a prediction equation in repeated random sampling (Mosteller & Tukey, 1977).

Unfortunately, the data needed to obtain unbiased estimates of the true relationship between a predictor and criterion are seldom available as random samples from the population of interest. Typically, samples from the bivariate or multivariate distribution of predictor(s) and criterion are available only for the subpopulation that satisfies the selection rule being validated. A medical school entrance exam may yield scores for the entire applicant pool, but grades exist only for the students still enrolled when the validity data are gathered. The selection effects present in these data may involve either explicit selection on the predictors or criterion, or a more complex phenomenon. Careful analysis of the sampling conditions that produce the data for a criterion-related validity study can reveal selection to be multivariate and even probabilistic in the sense that other potential influences on selection are unknown. These circumstances make estimating correlations and prediction equations problematic.

MODELLING SELECTION IN PREDICTION SETTINGS

If selection is multivariate and/or probabilistic, equations that predict the performance of future applicants based on a selected sample are biased. Specification error exists in the choice of predictors, i.e. the selection mechanism yielding the sample is not explicitly part of the prediction equation. Analytic procedures have been developed to adjust correlation coefficients and regression parameters for this type of specification error. The Pearson–Lawley corrections for range restriction due to explicit or incidental selection are the most widely used adjustments in education and psychology. In the simple case of explicit selection on a single predictor, the adjusted predictor–criterion correlation for the unselected population is

$$R_{XY} = [(S_X/s_X)r_{XY}]/[1 + (S_X^2/s_X^2 - 1)r_{XY}^2]^{1/2}, \quad (2)$$

where r_{XY} is the predictor–criterion correlation in the selected sample, and S_X and s_X are the predictor standard deviations in the unselected population and selected sample, respectively. Multivariate selection problems are discussed in Gulliksen (1987).

The Pearson–Lawley corrections belong to a group of methods that address specification error in regression models (Muthen & Joreskog, 1983). More recent approaches model the selection process with available surrogates for true selection variables (Rosenbaum & Rubin, 1983). These approaches estimate the probability of selection for each observation in the sample (a propensity score), and use that probability as a predictor in the regression equation. The propensity score can be estimated by regressing a dichotomous indicator (1 = selected, 0 = not selected) on the selection variables to yield an equation of the form

$$\text{logit}(p_i) = \gamma_0 + \gamma_1 Z_{i1} + \gamma_2 Z_{i2} + \gamma_3 Z_{i3} + \ldots + \gamma_q Z_{iq} + \epsilon_i, \quad (3)$$

where p_i is the probability of selection for person i and $Z_1, \ldots, Z_q$ are the explicit selection variables (note that a probit function can also be used). Including the propensity score as a predictor in equation (1) adjusts other parameter estimates for selection bias (Little & Rubin, 1987).

VALIDITY GENERALIZATION AND SITUATIONAL SPECIFICITY

A major concern in establishing criterion-related validity evidence is whether local conditions of test use influence the predictor–criterion relationship in such a way that validity evidence collected in one setting does not apply in another. This describes the hypothesis of situational specificity (Ghiselli, 1966). The methods of validity generalization expand the modelling described earlier to include distinct features of local validation studies and to estimate their influence on variation in criterion-related validity evidence.

The methods of validity generalization identify sources of variation in the correlations between predictors and criteria across validity studies. These include differences across studies in (1) sampling error, (2) range restriction, (3) predictor and criterion reliability, (4) validity of the criterion, (5) errors in the recording of data, (6) factorial composition of predictors, and (7) true situational specificity (Schmidt & Hunter, 1977). The first three of these are simply statistical artefacts that influence any criterion-related validity study; the others represent aspects of variation across studies with more complex implications for the validity generalization hypothesis. This hypothesis is tested by determining the proportion of variance in observed validity coefficients due to artefacts and then removing that variance from the interval estimate of the true validity of the predictor.

Since the early 1980s, empirical studies using these methods have repeatedly demonstrated that much of the variance in predictor–criterion correlations can be explained by statistical artefacts. However, the estimates of cross-study variance are based on assumptions about, for example, the independence of errors in estimating validity coefficients or the comparability of predictors and criteria across studies (Hedges, 1988). The 1999 *Standards* recommend clear articulation of these assumptions when relying on the results of a validity generalization study as support for local use of a test for prediction, selection, or placement.

The sensitivity of validity generalization procedures to violated assumptions has been considered by Hartigan and Wigdor (1989). Like any meta-analytic technique, validity generalization relies on samples of available criterion-related validity studies for inferences about true validity. Hartigan and Wigdor argue that few such samples are randomly drawn from a population of settings in which the test's validity for selection, placement, or clinical diagnosis is of interest. Sampling conditions, such as a tendency toward higher validity coefficients in published studies, can produce unknown biases in inferences from validity generalization studies. When results are used to support the local use of a test, the similarity of the local setting to the effective population sampled is critical.

For the most part, the methods of validity generalization have been used in analyses of correlation coefficients because the measurement units of predictors and criteria may be only roughly comparable across studies. Although these methods have been extended to regression slopes and intercepts, studies of the generalizability of regression equations have been limited because of the need for comparable predictor and criterion units of measurement. These conditions do occur in academic settings with a common, nominal grading scale or in organizations such as the military in which multiple training sites use the same predictor and criterion measures. Bayesian and empirical-Bayesian methods have been developed for estimating slopes and intercepts across colleges or training sites in these cases (Novick, Jackson, Thayer & Cole, 1972; Braun, Jones, Rubin & Thayer, 1983). Such methods use prior distributions on the parameters to shrink estimates of slopes and intercepts toward common values across studies.

DIFFERENTIAL PREDICTION AND PREDICTIVE BIAS

Uses of tests for prediction, selection, and clinical diagnosis require demonstration of dependable relationships between predictors and outcomes for examinees with different background characteristics. In some prediction contexts, the

influence of background variables is critical to a classification function the test might serve; in others, it is inimical to fair test use.

In clinical diagnosis or job placement, criterion-related validity hinges on the test or test battery discriminating among individuals in need of different treatments or better suited for particular job training programmes. This type of *differential* prediction (i.e. a test's ability to measure accurately differences among individuals that suggest distinct courses of action) requires several types of empirical evidence related to the probability of correct classification. If a profile of test scores is used to recommend a psychological treatment, then the reliabilities of differences between tests are of interest. Correlations with external variables that support the convergent and discriminant validity of the profile, usually considered as an aspect of construct validation, become inseparable from the battery's effectiveness in placing individuals in appropriate treatment categories. Adequate reliabilities of difference scores and patterns of correlations with external variables consistent with clinical outcomes together suggest the validity of a classification function based on profile scores.

The influence of background characteristics in predicting criterion performance of candidates in personnel selection or college admissions can have a direct impact on the fairness of a single selection rule for all candidates. Thus, the criterion-related validity of a test-based decision should be supported by analyses of differences between prediction systems for subgroups of an applicant pool defined by gender, ethnicity, or other demographic characteristics of social importance to fair selection. Prediction systems might differ in the conditional variance of criterion scores given the predictors, or in the slopes and intercepts of the prediction equations. The former suggests greater certainty in decisions made about members of one group because there is less chance of error in the prediction system for that group. The latter suggests predictive bias, namely that the expected criterion scores for members of each group differ systematically depending on whether predictions are based on a within-group or combined-group regression equation (Cleary, 1968).

Although empirical studies have demonstrated contrasting prediction systems within an organization for groups defined by gender or ethnicity, attributing the differences to predictive bias or showing the systems are unfair has been difficult in practice. Comparisons of within-group regression equations are limited by the same real-data problems as criterion-related validity studies in general. Statistical artefacts such as differential range restriction can produce apparent differences between prediction systems (Linn, 1983). Moreover, when differences are stable, combined-group equations often favour the focal group in the comparison by yielding predicted scores higher than those based on the within-group equation. The type and quality of the criterion measure (e.g. a hands-on measure of job performance vs. a test of job knowledge) can also influence differences between prediction systems (Wigdor & Green, 1989).

FUTURE PERSPECTIVES AND CONCLUSIONS

Local criterion-related validity studies serve important purposes despite the methodological concerns discussed. A well-designed local validation study clarifies local norms for test and criterion performance as well as local standards for selection and placement. Such studies are essential in the high-stakes testing environments that have become common place in psychology and education. Without this information, it is difficult to evaluate the possible effects of statistical artefacts on assessments of criterion-related validity, let alone know the extent to which situational specificity exists. Recognizing the limits of local validation helps to establish an interpretive framework for understanding and using test results, drawing from other perspectives on test validity described in this volume. Even if a local validation effort fails to produce conclusive evidence on the defensibility of selection, placement, or clinical practices, its role in clarifying the issues to be resolved remains important. In this context, combining the results of local validation efforts with knowledge from generalized validity builds the foundation of criterion-related evidence required by the 1999 *Standards* and needed to make informed decisions from test results.

V VALUES

INTRODUCTION

The goal of this entry is to summarize current approaches to human values assessment. Values are (1) beliefs about preferable end states or behaviours, and (2) internal criteria that guide information processing, evaluation of the internal and external world of a person, and selection of behaviour. Values are part of the system of personal meanings, including personal identity and purpose in life.

The entry begins with a summary of theories of values and methodological dilemmas concerning the measurement of values. Following this, selected measures are described and the entry ends with a short review of current research trends and future perspectives in the field of value assessment.

THEORY AND DEFINITION OF VALUE

There have been two general and contrasting approaches to the study of human values: an objectivistic and subjectivistic approach. According to the objectivistic approach value is an autonomous property: an objective quality inherent in the structure of reality which can be recognized and described (realism – Aristotle, Aquinas), or a metaphysical idea which cannot be observed, but which is knowable by intellectual

intuition (idealism – Plato, Sheler). From this point of view, a person lives in a world of values which are given, and human recognition of values can be in agreement or in disagreement with the objective order of values.

According to the subjectivistic approach human values are the results of a valuing process. One of the most important characteristics of a human being is an ability to create values of different kinds: spiritual values like moral, aesthetic, cognitive, and religious ones, or economic and material values.

This basic distinction can give rise to controversy about the status of value judgements which can be right and true or wrong and false, or which are arbitrary and incapable of any justification. A social scientist's approach to the study of values is usually derived from the subjectivistic conception, for the main subject of his or her study is the personal (subjective) construction of the world. Thus, in social sciences, a value is a belief about what is good or bad, right or wrong, worthy or unworthy, desirable or undesirable, and so forth. However, on the social or cultural level values are treated as intersubjectively valid conventions – 'objective' – which means that values on a collective level are shared by groups of people and/or organizations.

According to economic criteria which influence the current theory of values, value is the worth of a thing, and valuation is estimation of this worth. In psychology, values are defined in terms of beliefs about preferable end states or behaviours, and/or internal criteria that guide evaluation of the internal and external world of an individual and the selection of behaviour. The idea is expressed in a classic definition given by Kluckhohn: 'A value is a conception, explicit or implicit, distinctive of an individual or characteristic of a group, of the desirable which influences the selection from available modes, means, and ends of action' (1951: 395).

Personal values as beliefs are closely related to the self. Both cognitively and humanistically oriented writers have pointed to the general relevance of values for personality integration and well-being (Allport et al., 1960; Feather, 1975; Maslow, 1971; Rokeach, 1973). Values stand for a sense of continuity in life in spite of the changes, and in this way contribute to personal identity. The system of personal values underlies the process of meaning-making concerning oneself, the external world, and one's relation with it. Moreover, commitment in personal goals and strivings which are formulated in close correspondence to personal values contribute to our understanding of the world and provide the basis for meaning of life.

One of the most widely accepted definitions of value, as formulated by Rokeach, is as 'an enduring belief that a specific mode of conduct or end-state of existence is personally or socially preferable to an opposite or converse mode of conduct or end-state of existence' (1973: 5). Hofstede defines value as 'a broad tendency to prefer certain states of affairs over others' (1980: 15). Such values operate as criteria by which a person evaluates things according to their importance. The values influence selectivity of perception, information processing, and they provide non-specific guidelines for the selection of goals. Schwartz, who considers values as cognitive representations of human goals, proposed a comprehensive definition: 'Values (1) are concepts or beliefs, (2) pertain to desirable end states or behaviours, (3) transcend specific situations, (4) guide selection or evaluation of behaviour and events, and (5) are ordered by relative importance' (1992: 4).

VALUES ASSESSMENT: WHAT TO MEASURE AND HOW TO MEASURE?

Basic assumptions concerning the nature of values affects the way in which values are assessed. Morris (1956), for example, proposed a distinction between *operative values* which function as criteria for estimation of stimuli and choices, and *conceived values* which are beliefs about what is preferable or desirable in life. Such a conceptual distinction is reflected in value measurement. When values are defined as operative criteria underlying human choices, the best way to investigate such values is to observe respondents' decision making behaviour on the basis of their preferences. However, conceived values can be investigated by asking people to say which value is more important for them than others.

Another assumption concerns the organization of values by the individual. Assuming that values are hierarchical by nature, an ipsative design for their measurement has been proposed (Rokeach,

1973). The fact that personal values are integrated into a system has important implications for the study of values, which should cover a broad scope of values simultaneously considered by a person who, for example, is to rank them on the basis of their relative importance. This idea constitutes a main difference with assessment techniques in personality questionnaires in which the items are usually additive, and has been applied in numerous measures for value assessment. As Rokeach argues: '*life is ipsative*, because decisions in everyday life are inherently and phenomenologically ipsative decisions' (1985: 162), and moreover such methods are sensitive to stability and change.

In spite of the common agreement that values function as a whole system, the assumption about a necessarily hierarchical order of values is not universally accepted. The non-hierarchical view allows for a more flexible measure of values which are rated according to their importance on independent scales, and the person can use their full range (Morris, 1956; Schwartz, 1992).

Another methodological problem concerns the potential influence of social desirability which limits the reliability of values assessment. Self-report measures, especially concerning values, are prone to socially desirable responding, so the measures and specific results ought to be checked in this respect.

When a list consists of a number of values of different kinds, for example terminal and instrumental, there is a problem of possible shifting on the subjective scales of importance that respondents use when assessing values. In order to avoid this problem, anchoring techniques can be introduced prior to the rating of the values (Schwartz, 1992).

The ipsativeness of some value measures causes problems with validity and reliability, as well as with the statistical interpretation of the data. Extreme ranks are more valid and reliable than middle ranks. To overcome the limitations of possible statistical interpretation of the data from ranking (and pair comparison) design, scores need to be converted into an interval-scale.

MEASURES OF VALUES

Measures of values are merely verbal measures, in structured and self-report formats. The most commonly used designs are judgement and magnitude estimation. The former involves the ranking of a set of proposed values in a list of alternative responses, with a paired comparison task as a particular variant of this format. Magnitude estimation involves the rating of each of the values on a proposed list (Davis, 1991).

General measures cover a broad range of human values, and specific domain measures focus on a defined type of values, such as interpersonal or social values, work values, moral values, or values related to health.

The most well-known measures of values are introduced in Table 1. (For a description of some other scales see: Braithwaite & Scott, 1991; Davis, 1991.)

CURRENT RESEARCH TRENDS

Numerous psychological studies of human values focus on similarities and differences in value preferences of particular groups and/or nations (Feather, 1975; Hofstede, 1980; Rokeach, 1973).

Stability and change of values on an individual as well as a social level represent another extensively investigated subject matter. Both longitudinal researches and cross-sectional comparisons show that value priorities are relatively stable over the life span of individuals, and do not change very much in society across time and social changes.

Other research focuses on empirical classification of values and on the basic structure of value systems. Cross-cultural research in numerous countries reveals ten universal motivationally distinct types of values (see: Table 1; Schwartz, 1992), and the existence of underlying dimensions that organize value systems: Openness to Change versus Conservation and Self-Enhancement versus Self-Transcendence. On the other hand Hofstede (1980) has found four basic dimensions: power distance, uncertainty avoidance, individualism, and masculinity–femininity. The results obtained by Johnston (1995) suggest two general dimensions underlying both the terminal and the instrumental values measured by RVS: individualism-achievement and collectivism-affiliation.

Some studies concern the relationship between values and traits, attitudes, or goals (Bilsky & Schwartz, 1994). One of the most intriguing questions deals with the relationship between

Table 1. The most important instruments for assessing values

Author	Method	Scales/Content	Items	Format
Charles Morris (1956)	The Ways of Living	13 'ways of living'; for example: 'cultivate independence, show sympathetic concern, wait in quiet receptivity'	Each way of living is described in a few sentences and represents a conception of a desirable life articulating definite value orientation	Rating: from 7 – 'I like it very much', to 1 – 'I dislike it very much'
Gordon W. Allport, Philip E. Vernon, Gardner Lindzey (1960)	The Study of Values (SV)	Six scales corresponding to six types of values: theoretical, economic, aesthetic, social, political, and religious	45 questions about preferences based on comparisons: part I – 30 questions with two alternative answers; part II – 15 questions with four possibilities. Each value enters 20 times.	Part I: indicating preferences by distribution of 3 points between two answers (3 and 0, or 2 and 1) Part II: ranking four possibilities from 4 – the most preferred, to 1 – the least preferred
Milton Rokeach (1973)	The Rokeach Value Survey (RSV)	Two lists of values: terminal values referring to desirable end states, and instrumental values referring to means and modes of human conduct	Two lists of 18 values; each value is described by label and explanatory phrase. Examples of terminal values are: comfortable life, equality, freedom, salvation, true friendship; examples of instrumental values are: clean, forgiving, helpful, honest, responsible.	Rank-ordering each set of values: from 1 – most important to 18 – least important
Shalom H. Schwartz (1992)	The Schwartz Value Survey (SVS)	Ten universal types of values: Power, Achievement, Hedonism, Stimulation, Self-Direction, Universalism, Benevolence, Tradition, Conformity, and Security	56 specific values defined in terms of general motivational goals; the values are named, with explanatory phrases in parentheses	Rating each value 'as a guiding principle in my life', using a 9-point scale: from 'supreme importance' (7), to 'not important' (0) and 'opposed to my values' (−1)
Leonard V. Gordon (1976)	The Survey of Interpersonal Values	Six interpersonal values: support, conformity, recognition, independence, benevolence, and leadership	30 sets of three statements	Choosing the most and the least important alternative

(*Continued*)

Table 1. Continued

Author	Method	Scales/Content	Items	Format
George W. England (1975)	The Personal Values Questionnaire (PVQ)	Two main value orientations in managers: pragmatism and moralism	66 concepts, such as productivity, my coworkers, or ambition, related to two main values	Rating the concepts on two dimensions: importance – high, average, or low, and meaning – the degree to which the concept is pleasant, right, or successful
Donald E. Super (1970)	The Work Values Inventory (WVI)	15 scales designed to measure values related to work motivation; for example: achievement, associates, creativity, economic return, and prestige	45 items; each scale has three items referring to work related values	Rating according to importance, using a 5-point scale

values and behaviour, and takes that as a starting point for possible prediction of goal activities undertaken by the person. Research in this field draws attention to modification of values, and, as a consequence, attitudes and behaviours, through a self-confrontation procedure. This method is based on cognitive dissonance between one's own preferences and the preferences of a particular reference group.

It is also possible to assess values by referring to ego development, self-actualization, self-transcendence, or psychological maturity. All these notions presume a definite role of a personal value system and valuation process in motivation and personality functioning. Such studies are often founded on the phenomenological-existential notion that one's life can be regarded as meaningful, when a person is able to find a relation between his or her behaviour and values. Similar methods deal with value systems of personal ideologies, ethical attitudes, and moral reasoning.

Research concerning work values has pointed to the relevance of value congruence between the person and organization. Organizational work values influence the choice of work and function as predictors of success in organizational settings. Other studies focus on the structure of values, value profiles and patterns, and value change (Roe & Ester, 1999).

FUTURE PERSPECTIVES

To compare the value systems among different groups of people, often originated from various nations or cultures, we need to examine the homogeneity of their preferences prior to intergroup comparisons. The reason for avoiding group comparisons, defined a priori by such variables like sex, age, or education, is that measures based on a central tendency can disguise real preferences or even value orientations of the subgroups in a given sample (Pitts, 1981).

Current methodological explorations are concerned not only with the validity and reliability of different value measures or the potential influence of social desirability on values assessment but also tend to develop new instruments based, for example, on a circumplex model (Locke, 2000). Current studies also search for new possibilities of psychometric and psychological interpretation of values and valuation by means of structural equations, multidimensional scaling and smallest space analysis (SSA), used for example to identify the underlying subset of values (Schwartz, 1992).

Asking for more specific interpretation of otherwise general values allows for comparisons among the personal worlds of different people and even among the worlds of different cultural

groups or communities. If on the methodological level people have the opportunity to express their specific interpretations of values, there is more chance that personal or cultural differences, as expressed in their own language, are revealed.

In the future the researcher can pay more attention to unique meanings of common values. As Hermans and Hermans-Jansen argue: 'each common value of each group is interpreted, more or less consciously, by each individual as part of his or her own personal narrative (i.e. valuation system)' (1995: 21). In cross-cultural or intra-group comparisons we are accustomed to referring to collective meaning of each value, like freedom or love. However, on an individual level we refer to personal interpretation of values (Hermans & Oles, 1994). Personal valuation refers to construction of a system of personal meanings, containing cognitive interpretations of personal experience combined with affective connotation. As the process of valuation includes cognitive, affective and motivational aspects of valuing, questions regarding the relationship between values and activities expressed in personal projects (Horley, 2000), or worries defined as increasing attention and perception of threats to valued goals (Schwartz et al., 2000), can be addressed. Currently developed measures designed to investigate disorganization of personal valuation (Hermans & Oles, 1996; Oles, 1991) tend to measure values indirectly by assessing virtues (Cawley III et al., 2000), or operating life philosophy (Boyatzis et al., 2000).

CONCLUSIONS

Over the past decades an interest in the problem of values has remained and has even grown. The psychological approach to value assessment deals with one of most prominent human phenomena: the ability to value. Despite the complexity of the subject under investigation researchers use rather simple methods for answering the questions arising in this field. Over the years, the design of the measures (ranking, or rating procedure) has not changed very much. The interest of researches, however, tends to change from the assessment of a priori defined values or value orientations to discovering basic or latent dimensions of value systems, on the one hand, and to the process of personal valuation, on the other hand.

V VISUO-PERCEPTUAL IMPAIRMENTS

INTRODUCTION

The assessment of visuo-perceptual impairment after acquired brain injury is a difficult task in clinical practice. There are different reasons for this, the first being that, unless the deficit is so evident that it becomes a handicap for everyday living, many people who are visuo-perceptually impaired are normally not even aware of their impairment. Second, the tests and tasks used to evaluate or assess visual and perceptual functioning may lack the necessary accuracy to be able to detect subtle variations. Third, organizing a precise and effective neuropsychological assessment of visuo-perceptual functions requires a thorough understanding and knowledge of the concept and theory regarding these functions. And fourth, people sustaining brain injury normally have cognitive, emotional, and behavioural disorders that normally interact with the visuo-perceptual deficit, especially attention, language, memory, and motor impairments. The correct neuropsychological assessment of these functions requires a trained neuropsychologist with expertise in this field.

The assessment of visuo-perceptual functioning must be preceded by a careful neuro-ophthalmological examination of the most elementary components of vision. This is due to the fact that visual defects may be confused with visual agnosic problems. In addition, it is necessary to delimit elementary and higher visual functions which are not always clearly differentiated.

The neurological exploration of visuo-perceptual functioning must include:

(a) Examination of visual fields.
(b) Assessment of visual perception of objects and pictures.
(c) Assessment of visuo-spatial orientation.
(d) Assessment of colour perception recognition.

(e) Assessment of visual scanning.
(f) Assessment of neglect.

THE EXAMINATION OF VISUAL FIELDS

In neuropsychology, the examination of the visual fields is important in order to detect hemianopsia and quadrantanopsia. Examination of visual fields is generally carried out in neuro-ophthalmology through perimetry in a task in which the patient maintains his/her gaze on a fixed point and must detect the appearance of a stimulus in another part of the perimeter of the visual field. The patient must therefore simultaneously perceive two points. After certain injuries to the occipital cortex, the ability to perceive two points simultaneously is impaired and such patients can only perceive one stimulus at a time. However, it is important to take into account that the results of visual field perimetry testing may be affected by attentional problems. In such cases, mistakes may be more determined by the attentional disorder than by visual field problems.

Another important part of the neuro-ophthalmological examination is the examination of eye movements and of the direction of the gaze, especially the elementary or reflex movements and the complex or psychomotor movements. The *reflex movements* examined here consist of a reflexive tendency to fix and follow the gaze on a point or object situated in the central visual field as the object moves to the right or to the left. This type of eye movement is associated with the lower part of the brain stem and the cortical posterior oculomotor centres. The *psychomotor movements* are studied in a more complex task, in which, for example, the patient must move the gaze to the opposite side of the object as the object remains in the visual field. These movements are associated with the anterior oculomotor centres of the brain and to the anterior zones of the frontal lobes which connect to these oculomotor centres. The examination of eye movements may be done clinically as well as by means of different electroencephalographic methods.

The Seville Neuropsychological Battery (BNS) (León-Carrión, 1998) includes the assessment of hemianopsia and hemi-inattention. A computer-adapted tachistoscopic letter cancellation test was developed in order to assess inattention and hemianopsias. The subject maintains the gaze fixed on a white point that appears at the centre of the computer screen while different letters appear in the centre of each of the four quadrants into which the computer screen is divided. The subject must not shift the gaze from the central white point and should press the space bar only when the letter 'O' appears.

The task is made up of three sub-tests: tachistoscopic attention of both eyes, tachistoscopic attention of the right eye and tachistoscopic attention of the left eye. In the first sub-test, the subject must use binocular vision, while in the second and third sub-tests, monocular vision of first the right, then of the left eyes are assessed separately. Using a discriminant function technique, Perez-Gil and Machuca (1999) reported a prediction rate of 66% of patients with brain injury, both severe and mild and normal controls. In a study by Tellado et al. (1999) a clear tendency of Alzheimer's Disease patients to commit a greater number of omissions was observed, thereby identifying a lower number of elements in the tachistoscopic tests that make up the BNS.

ASSESSMENT OF VISUAL PERCEPTION AND RECOGNITION OF OBJECTS AND PICTURES

To assess the visual perception of objects and pictures, different consecutive activities are examined. These activities examine the capacity to examine an object, to distinguish the essential features of an object and then to integrate these features into a pattern, the capacity to discriminate essential and non-essential characteristics, and the capacity to self-correct failed analysis.

The most relevant tests for the evaluation of visual perception and recognition of pictures and objects follow:

(a) *Luria/Christensen's Investigation of Higher Visual Functions* (Christensen, 1975). This test, which evaluates visual reception, is a qualitative clinical analysis of the perception of objects and their pictorial representation and the analysis on the basis of visual agnosia. The subject must first carefully examine different pictures of

simple clear objects and later identify complicated or confusing objects. Then pictures of scribbled objects, or of overlapping figures, must be examined and named (as Poppelreuter Overlapping Figures, 1917). Other times the subject will perform a few examples of Raven's Coloured Progressive Matrices Test (1965). People with occipital-parietal or frontal lesions, or with lesions in the right hemisphere, tend to err on these tests. No psychometric data has been provided because in the experimental and clinical traditions the Luria/Christensen Investigation yields more than in the psychometric tradition.

(b) *Recognition of Pictured Objects* (Warrington & Taylor, 1973). In this task subjects must identify familiar objects under two distorting conditions. The first condition is made up of 20 drawings that have been enlarged. The second condition is made up of 20 familiar objects photographed from a conventional and a non-conventional perspective.

(c) *Other tests*. There are other tests which evaluate visual perception and recognition such as the Face Recognition Test (Warrington and James (1967), the Test of Facial Recognition (Benton & Van Allen, 1968) or the Visual Form Discrimination Test (Benton et al., 1983). There are also tests designed to evaluate visual organization which use ambiguous, incomplete, fragmented, or fragmented and distorted figures. Examples of these are the Street Completion Test (Street, 1931) and the Hooper Visual Organization Test (Hooper, 1958). The Hidden Figures Test (Thurstone, 1944) evaluates visual organization using visual interference.

ASSESSMENT OF VISUO-SPATIAL ORIENTATION

Visuo-spatial orientation is assessed by evaluating the individual's ability to orient in space: up and down, right and left. Tests assessing these functions involve the analysis of spatial relationships and the arrangement of the lines which compose familiar figures, or discovering the similarities and differences between mirrored lines and figures, or drawing these figures, and so on. A similar task involves analysing the positions of the hands of a clock. Other tasks evaluate spatial orientation by showing the patient a map and asking for directions, asking the subject to draw a plan of his/her room, or to plan the route one would take to go from the office to the building's exit, and so forth.

ASSESSMENT OF COLOUR PERCEPTION AND RECOGNITION

The ability to selectively sense different light wavelengths allows the visual system to create the perception of colour. Colour vision is determined by the perception of the complex interactions of the proportions of wavelengths reflecting from a surface and the intensity of light. The areas involved in colour perception are the upper regions of both the left and right visual fields and the lower secondary pathway from the visual area in the occipital lobe to the temporal lobe.

Different tests can be selected for the assessment of colour perception and recognition. Among the more commonly known classic tests are:

(a) *The Farnsworth–Munsell 100-Hue and Dichotomous Test for Colour Vision* (Farnsworth, 1943). The patient must sequentially order colours which have subtle differences. Although this is a difficult task, it is very useful as it includes non-verbal assessment of any problems with pure sensory perception of colour.

(b) *The Colour Perception Battery* (De Renzi & Spinnler, 1967). This is a short battery that includes the Ishara plates, colour matching, colour naming, pointing to colour, memory for colour, and colour drawing. This battery seems to have a good discrimination validity.

(c) *Colouring of Pictures and Wrongly Coloured Pictures* (Damasio et al., 1979). This was created to distinguish colour agnosia from colour anomia. It consists of choosing a crayon from a multicoloured set and fill in drawings of a familiar figure with its own appropriate colour (e.g. banana with yellow). In the Wrongly Coloured Pictures Test subjects must name the wrong coloured pictures.

ASSESSMENT OF VISUAL SCANNING

Traditionally, visual scanning is assessed by means of two tests:

(a) *Elithorn's Perceptual Maze Test* (Elithorn et al., 1964). This test consists of a series of triangular or rectangular V-shaped lattices with dots randomly placed at various intersections of the lattice. The subject must find a pathway starting from the bottom towards the top and pass through as many dots as possible. The test highly correlates with both verbal and non-verbal intelligence tests and is very sensitive to brain damage, especially to lesions of the right hemisphere. This test is more related to the experimental tradition than to the psychometric tradition. Nonetheless, the test–retest correlation has been informed as 0.81.

(b) *Talland's Line Tracing Task* (Talland, 1965). This task is very similar to those found in line-mazes in the cross-word puzzle section of the newspaper. It consists of asking the subject to find, among all the lines, which is the one that connects one object to another.

ASSESSMENT OF NEGLECT

Clinicians define neglect as failure of the individual to report, respond to, orient towards, or interact with objects or people generally (but not always) situated in the visual field opposite to the hemisphere in which the brain lesion is located. Left neglect after right brain damage is more common than right neglect. Normally, people with neglect have problems with objects situated on the left side, in dressing and washing his/her left side, in eating from the left side of the plate, in seeing the left part of drawings, and so forth. It is insidiously disruptive and affects daily living activities. Hemi-inattention is another term used to refer to a patient's failure to attend or respond to a stimulus specific to a hemifield.

Cancellation tests are the most common tasks used to assess neglect and among them Bells Test (Gauthier et al., 1985) and Start Cancellation (Hallingan et al., 1991) are widely used. In this type of test, patients must localize and cross out or tick different-sized letters or stars, or a letter, star or word of a given size on a page covered with letters or words. Generally, individuals with hemi-inattention will neglect the targets situated in a hemifield of the page. The Assessment of Inattention and Neglect from the Seville Neuropsychological Test Battery (León-Carrión, 1998) is a computerized tachistoscopic test in which subjects must detect the letter 'o' when it appears in the centre of one of the four quadrants into which the computer screen has been divided. Another test used for assessing neglect is the Line Bisection Test (Schenkenberg et al., 1980), in which the patient is asked to bisect a 20 cm line drawn on an A4 paper. Abnormality is considered for a bisection point of 6.5 mm or more from the midpoint. In the Clock Drawing Task the patient is asked to draw the face of a clock from memory; failure to draw a complete circle with the numbers 1–12 written and spaced inside the circle is considered abnormal. Another test is the Behavioural Inattention Test (Wilson et al., 1987).

FUTURE PERSPECTIVES AND CONCLUSIONS

Disorders of visuo-spatial perception, visual agnosia, and neglect are common neurological illnesses and a great many patients are not aware of having these disorders. Even though current neuropsychological testing and clinical exploration are very useful in detecting these disorders, during the coming years the relationship that exists between the nature of neglect, the localization of the lesion, and the sensitivity and specificity of the neuropsychological tests currently in use should be established. This is important given that some of these tests may be measuring different aspects of visuo-perceptual disorders.

V VOLUNTARY MOVEMENT

INTRODUCTION

Voluntary movements are the only means by which the human mind can communicate with the outside world and other minds. Be it speech, facial expression, manipulation of objects, gesturing or simply pressing a button – the mind cannot manifest itself otherwise than by directing movements of the body. Consequently, the range of behaviours that could be subsumed under the heading 'voluntary movement assessment' is infinite.

This entry will concentrate on a very limited range of motor behaviours which neuropsychological tradition considers as giving rise to 'high level' disorders of motor control. They are summarized in Table 1. The rather vague and ill-defined term is meant to signify that disorders are neither purely motor nor purely mental but arise at the interface between mental processes and motor control or, respectively, between the mind and the body.

One class of such disorders is frequently subsumed under the term 'apraxia'. They are

Table 1. Summary of voluntary movement disorders

Disorder	Assessment
Apraxia	Presentation of meaningless gestures for imitation Verbal request for demonstration of meaningful gesture Presentation of tools and objects for demonstration of use
Grasping and groping	Presentation of stimuli in immediate vincinity of hand
Utilization behaviour	Presentation of tools and objects without instruction to use them
Imitation behaviour	Presentation of gestures or actions without instruction to imitate them

characterized by spatially misoriented or awkward movements. Other than in 'elementary' motor disorders the same movements which give rise to errors in one condition can successfully be performed in other conditions and success or failure depend on factors not directly related to motor control. Such factors may be the communicative meaning of a gesture or its relationship to tools and objects. Another class of 'high level' motor problems is constituted by well executed and apparently purposeful movements which do not conform to the subject's intentions.

Even this restricted range of motor behaviours is very heterogeneous. There is thus no standard assessment for all of them. Selection of appropriate diagnostic measures depends on the examiner's conjectures of likely disturbances in the individual patient. These are guided by knowledge of the brain – behaviour relationships, by the patients' own complaints and by observation of their spontaneous behaviour.

APRAXIA

The concept of apraxia was elaborated by Hugo Liepmann (1908) nearly a hundred years ago. Liepmann noted that patients with left sided brain damage committed errors when performing motor actions with either hand. Most of these patients were also aphasic but he found apraxic patients without aphasia, and argued convincingly that faulty motor actions could not be explained as being a sequel of language impairment. He proposed instead that only the left hemisphere is capable of translating a concept or mental image of a desired action into appropriate motor commands. The nature of left hemisphere motor dominance and its relationship to language gave rise to various conflicting interpretations and remains an unsettled question after 100 years of research (Rothi et al., 1997; Heilman & Rothi, 1993; De Renzi, 1990; Geschwind, 1975; Kimura & Archibald, 1974).

Three kinds of actions are traditionally investigated for a clinical diagnosis of apraxia, because they yield clear manifestations of apraxic errors: imitation of gestures, demonstration of meaningful gestures, and use of tools and objects.

Imitation of Gestures

Patients understand the request to imitate (if they do not, apraxia cannot be diagnosed) and try to attain a gesture resembling the demonstration, but the resulting posture is spatially wrong. The problem concerns the definition of the target posture rather than its motor execution, and patients commit errors also when asked to replicate the gestures on a mannikin or to match photographs of the same gestures performed by different persons seen under different angles of view (Goldenberg, 1995, 1999).

Clinical Assessment

It is preferable to test meaningless gestures as they give an uncontaminated insight into the ability to imitate the shape of gestures. Imitation of meaningful gestures may be accomplished by recognition of their meaning and subsequent reproduction without copying the shape of the gesture. The examiner sits opposite the patients and demonstrates the gestures 'like a mirror' using the right hand for left hand imitation and vice versa. Patients should always use the hand ipsilateral to the lesion. They are allowed to start imitation only immediately after demonstration. The severity of impairment may vary according to which body parts are involved. Whereas imitation of hand postures is impaired only in patients with left brain damage, imitation of

finger postures and – to a minor degree – also foot postures is sensitive to both left and right brain damage (Goldenberg, 1996).

Meaningful Gestures

Patients are unable to demonstrate meaningful gestures on command. Such gestures may either have a conventionally agreed, more or less arbitrary, meaning like 'somebody is nuts', 'military salute', or 'okay', or they may indicate objects by miming their use. Outside the testing situation the deficit can be observed when aphasic patients try to express themselves in spite of severe language impairment. They either do not employ gestures at all or produce amorphous and incomprehensible gestures.

Clinical Assessment

Usually, diagnosis concentrates on miming of object use, because aphasic patients may not understand the verbal label of gestures with conventional meaning, whereas comprehension of the object name can be facilitated by showing either the object (e.g. a hammer, a key, a screwdriver) or a picture of it. Even with this help, understanding of the instruction may be problematic. A diagnosis of apraxia should be made only if patients respond to the presentation of the object with a movement of the hand which can be clearly distinguished from spontaneous 'baton' movements accompanying attempts of verbal expression. A further difficulty is posed by the great variability of gesture performance in normal subjects. For example, the replacement of the absent object by the hand ('body part as object': e.g. brushing teeth with the index rather than demonstrating the manipulation of a toothbrush) is a strategy frequently employed to indicate an absent object when the verbal label is lacking (e.g. when trying to buy a toothbrush in a country the language of which one does not speak). There are, however, errors which unequivocally indicate apraxia:

- Perseveration of a more or less amorphic movement (e.g. a circling movement above the table or repeated hitting of the fist against one's chest).
- Pointing to the location where the object should be applied (e.g. pointing to the mouth for a toothbrush or to the table for a pencil).
- Searching movements of the hand and fingers which eventually result in a recognizable pantomime ('conduite d'approche').

Use of Tools and Objects

Use of tools and objects is awkward and faulty. For example, patients press the knife perpendicularly into the loaf rather than making a slicing movement or press the head of the hammer upon the nail and turn round rather than hitting the nail. Difficulties increase when patients perform chains of actions involving multiple tools and objects (e.g. preparing a meal), and when actions require comprehension of technical and mechanical constraints and mechanical problem solving (e.g. fixing household repairs or handling unfamiliar electronic equipment).

Clinical Assessment

Patients are presented familiar objects like a padlock with a key, a hammer and a nail, a comb, or binoculars and are asked to use them. More demanding probes are to provide a sheet of paper, a perforator, and a folder, and to ask the patient to punch the paper and insert it into the folder, or to ask the patient to put together a pocket lamp from its parts. Multi-step actions involving several objects like preparation of coffee or a meal and performance of technical tasks put demands on memory and executive function over and beyond specific knowledge of tool and object use (Schwartz et al., 1999).

Kinematic Measurement

Clinical assessment of apraxia can be complemented by kinematic registration of the path and temporal evolution of movements (Bizzi & Mussa-Ivaldi, 1990; Jeannerod et al., 1995). Abnormal kinematic features have been documented when patients with apraxia imitated movements or performed pantomime of object use (Poizner et al., 1995; Hermsdörfer et al., 1996), but it is not sure whether they reflect disturbed motor control. It may be that difficulties arise at a higher level and concerns not motor control but the determination of the target which should be reached by appropriate motor actions. Degradation of

movement kinematics may be due to subsequent hesitancy and insecurity and thus be a reaction to rather than the cause of problems.

MOTOR ACTIONS NOT CORRESPONDING TO SUBJECTS' INTENTIONS

Grasping and Groping

When getting in touch with an object, the affected hand grasps it. It may also grope for visually perceived objects located in its proximity and grasp them. Few patients are able to suppress the grasp reaction by an effort of will. The majority have to interfere with their sound hand to loosen the grasp. They may sit on their hand or permanently place an object into it to prevent it from clenching external objects.

Clinical Assessment

The examiner moves a finger or a comparable object over the palm exerting some pressure on skin. The patient's hand will grasp it even when explicitly advised not to do so. For eliciting groping an object is held close to the patient's hand and slowly withdrawn. The hand follows the object in spite of an explicit advice not to do so.

Utilization Behaviour

Patients use objects which happen to be within their grasp in a way which is appropriate to the object but not to the situation. For example, they may take glasses which the examiner has laid down and put them on their nose, or they may take a stamp and repeatedly press it on a sheet of paper.

Clinical Assessment

Care must be taken to distinguish utilization behaviour from enhanced suggestibility of brain damaged patients. If, for example, the examiner interrupts testing and puts objects on the table without commenting on their purpose and waits for the patient's reaction (Lhermitte, 1983), patients may understand this as a non-verbal invitation to use the objects. It is therefore preferable to have attractive objects (e.g. glasses, matchbox, cigarettes, a pack of cards, a filled bottle and a glass) installed in the periphery of the table already when the patient enters the room, to engage the patient in an unrelated conversation or test, and to observe their spontaneous behaviour (Shallice et al., 1989).

Imitation Behaviour

Although not requested to do so, patients imitate gestures and actions of the examiner or other persons. For example, patients may take off their glasses when the examiner does so or repeat back questions rather than answering them. An explicit command not to imitate can stop imitation but introduction of a pause is sufficient for reappearance of imitation. When asked why they imitated patients are puzzled and say nothing or they claim that they thought this was the implicit request made by the examiner (De Renzi et al., 1996).

Clinical Assessment

The diagnosis rests mainly on observation of spontaneous behaviour during conversation and testing. Avoidance of non-verbal requests to imitate can be very difficult when gestures are introduced explicitly for provoking imitation behaviour.

FUTURE PERSPECTIVES AND CONCLUSIONS

The selection of topics for this entry may be accused of a certain arbitrariness. It might be argued that utilization and imitation behaviours are behavioural rather than motor problems while reaching and grasping may be considered as demanding high level motor control and hence deserving inclusion in this entry too. Possibly, this arbitrariness points to the deeper problem of distinguishing between mental processes and their motor expression. The delineation and assessment of disorders of voluntary motor control depends heavily on theoretical models of brain behaviour relationships. It is likely that further evolution and progress of cognitive neuroscience will change the daily routine of clinical assessment of voluntary motor disorders.

WELL-BEING (INCLUDING LIFE SATISFACTION)

INTRODUCTION

Over the past quarter century, measures intended to assess Subjective Well-Being (SWB) have substantially increased, in terms of both the number of measures available and the sophistication of these measures. In this entry, we will briefly review a selected sampling of such measures, as well as some of the issues surrounding assessment in this domain. After defining the relevant constructs, we will present sections on measurement issues, measures of life satisfaction, measures of positive affect, general measures of well-being, and measures of low negative affect. A section focused on future issues and directions will be followed by a final section of conclusions.

DEFINING SUBJECTIVE WELL-BEING

Most investigators engaged in research on SWB conceptualize it as a multi-faceted domain of interest, rather than as a unitary construct. A representative definition is provided by Diener, Suh, Lucas, and Smith (1999): 'Subjective well-being is a broad category of phenomena that includes people's emotional responses, domain satisfactions, and global judgments of life satisfaction' (p. 277). People's emotional or affective responses (including both moods and emotions) represent 'on-line' (Diener, 2000: 34) evaluations of events that are happening to them. Judgements of life satisfaction represent broader, more cognitively based evaluations of one's life as a whole (Pavot & Diener, 1993), and domain satisfactions represent evaluations of specific aspects of one's life (e.g. work satisfaction, marital satisfaction). These components often are substantially correlated; yet, when measured separately, they frequently account for unique variance when predicting overall SWB, and therefore are properly assessed independently with specifically dedicated instruments. Although early attempts at assessment often involved very simplistic measures (in many cases, a single item) intended to capture the whole domain of SWB, most contemporary measures incorporate multiple-item formats and are focused on only one component of SWB.

MEASUREMENT ISSUES

Researchers who intend to assess some aspect of SWB should be aware of a number of factors which could influence the validity of their efforts. In this section, we will briefly present some of the more prominent threats to validity, and suggest some possible methodological strategies which should serve to reduce these threats.

Reliability Issues

As noted above, many early efforts to assess SWB relied on a single item embedded in a multiple purpose questionnaire. Although single-item measures do appear to have some degree of validity,

their test–retest reliability is often relatively low (Schwarz & Strack, 1999), and their internal consistency is impossible to determine. For reasons of reliability, the use of single-item self-report measures of SWB should be avoided, where possible, in favour of multiple-item measures. Most contemporary measures of SWB incorporate a multiple-item structure, and as a consequence typically have good psychometric characteristics.

Contextual Influences

Summarizing evidence from a number of studies, Schwarz and Strack (1999) made a strong case that momentary mood states or relatively trivial contextual events (e.g. finding a dime) can influence reports of global SWB, under some circumstances to a substantial degree. Single-item measures of SWB are particularly vulnerable to momentary contextual influences. A methodological step that can serve to reduce the influence of momentary contextual effects is to assess the respondent's SWB on multiple occasions, rather than at only one point in time. These multiple assessments can then be averaged into a composite SWB score. This procedure can effectively reduce the effects of momentary contextual influences, assuming that the contextual influences at Time 1 are different than at Time 2, and so on.

Response Artefacts

As is true with all self-report measures, self-reported measures of global SWB can be influenced by response artefacts. Some response artefacts, such as impression management or social desirability, are of particular concern. In the case of impression management or social desirability, one strategy is to compare reports of SWB obtained in face-to-face interviews with reports obtained under anonymous circumstances (Diener et al., 1999). The usual strategies for reducing measurement error in other self-report instruments should be incorporated into designs assessing SWB as well.

Alternatives to Traditional Self-Report

Despite the fact that the predominant methodology in SWB research has been the use of traditional global self-report measures, recent studies have included measures that provide an alternative to traditional self-report. One important alternative is the Experience Sampling Method (ESM; Sandvik, Diener & Seidlitz, 1993). Using ESM techniques, respondents are cued (e.g. by a pager or palm computer) to respond, at random moments during their everyday routines, with brief reports of their immediate SWB. Typically, a relatively large number of such reports are completed, over perhaps a period of two to four weeks. Although they still represent self-report data, such assessments avoid many of the threats to validity discussed above, and begin to approach the optimal assessment technique of a continuous readout of emotional experience as discussed by Kahneman (1999).

Although the methodological details are beyond the scope of the present entry, other alternatives to self-report are worthy of mention. Physiological measures, ratings by informants, ratings of facial expression, and memory measures can serve as important adjuncts to self-reports of SWB by providing convergence and external validity for self-report measures (e.g. Sandvik, Diener & Seidlitz, 1993).

MEASURES OF LIFE SATISFACTION

Measures of life satisfaction generally fall into two categories: multidimensional or global satisfaction with life measures, and domain satisfaction measures. Global satisfaction with life measures usually are intended to assess the respondent's satisfaction with life as a whole, or, in the case of multidimensional measures, with a set of critical life domains. Domain satisfaction measures are focused on just one life domain, such as job satisfaction, marital satisfaction, satisfaction with housing, and so on. Domain satisfaction measures tend to be developed and used in rather specific research situations (e.g. research on marital quality), and as such may not be as broadly applicable as the global or multidimensional life satisfaction instruments. For this reason, we will offer examples of multidimensional or global life satisfaction measures only.

Prominent among the early life satisfaction measures from the gerontological/geriatric literature is the Life Satisfaction Scale (Neugarten, Havighurst & Tobin, 1961). Variants of this scale include the Life Satisfaction Index A (LSIA),

the Life Satisfaction Index B (LSIB), and the Life Satisfaction Rating (LSR). Each of these scales is multi-faceted; subsets of items are designed to measure each of several aspects of SWB (e.g. zest vs. apathy, positive self-concept, congruence between desired and achieved goals). These scales are most appropriate for the assessment of older adults.

The Satisfaction With Life Scale (SWLS; Pavot & Diener, 1993) was designed to assess an individual's satisfaction with life as a whole, rather than measuring satisfaction with specific domains such as work, marriage, or finances. The 5-item SWLS offers the advantages of a multiple-item measure, yet its brief format is sparing of time and space when it is incorporated into a battery of instruments. The SWLS has been shown to have good internal consistency and moderately high temporal stability, yet it has also been demonstrated to possess sensitivity to change, such as improvement during therapy (see Pavot & Diener, 1993). The SWLS is available in several languages, and has been used in a number of cross-cultural studies. The SWLS is suitable for the assessment of people from a wide range of ages, and educational levels. The scale, along with fairly extensive normative and cross-cultural data, is presented in Pavot and Diener (1993).

The Multidimensional Students' Life Satisfaction Scale (MSLSS; Huebner, 1994) is a 40-item measure designed to assess the life satisfaction of preadolescent students (Grades 3–5). Subscales of the MSLSS focus on the factors of self, school, living environment, friends, and family. The MSLSS has demonstrated good psychometric characteristics, and closes a significant gap by providing a measure of life satisfaction for this age group.

MEASURES OF POSITIVE AFFECT

Before presenting examples of measures of positive affect, it should be noted that most affect-focused measures include subscales measuring both positive and negative affect. Often, the scores for positive affect and negative affect are determined, and then the score for negative affect is subtracted from the score for positive affect. This difference score is usually referred to as affect balance (Bradburn, 1969), and can be used as a general index of SWB. However, some investigators prefer to use positive and negative affect scores separately, and not conflate them into a single index.

A ground-breaking measure of affect measurement is Bradburn's (1969) Affect Balance Scale (ABS). The scale consists of ten questions concerning affective experiences which the respondent may have experienced 'during the past few weeks' (five relating to positive affective experiences and five relating to negative affective experiences), to which the respondent provides a 'yes' or 'no' answer. Scores on the ABS typically are moderately correlated with other indices of SWB.

Kammann and Flett's (1983) Affectometer 2 was developed following the pattern of Bradburn's ABS, but the Affectometer 2 incorporates a frequency response scale, rather than relying on 'yes' or 'no' responses, and includes 40 items. Ten facets of SWB are assessed, with each represented by four items of the scale. The Affectometer 2 retains high internal consistency (coefficient alpha = 0.95) despite its multi-faceted design, and correlates well with other measures of SWB.

A more recent and frequently used measure of both positive and negative affect is the Positive and Negative Affect Schedule (PANAS; Watson, Clark & Tellegen, 1988). The positive affect and negative affect subscales of the PANAS include ten affective adjectives each; respondents report the degree to which they have experienced each of the emotions, over a specified time frame, on a 5-point scale. The time-frame instructions of the scale can be adjusted to prompt the respondents to report their immediate affective experience, or to reflect a longer period of focus (e.g. 'over the past few days', 'the past few weeks' or 'the past year'). The two subscales have good internal consistency, are substantially uncorrelated, and have demonstrated good convergent and discriminant validity (Watson et al., 1988), although they assess primarily high arousal and activation forms of affect.

An alternative set of affective adjectives, based on the pleasant/unpleasant dimension of the circumplex model of emotion, has also been used with good results in SWB research. Examples of these pleasant/unpleasant affective adjectives are presented in Diener and Emmons (1984). Several studies have demonstrated that

measures of life satisfaction and SWB tend to be located in the pleasantness octant of the mood circumplex, whereas personality characteristics relating to depression were found in the unpleasantness octant of the circumplex. This evidence suggests that adjectives clustering along either end of the pleasant/unpleasant affective dimension are more representative of SWB than adjectives derived from alternative rotations of affective space. Therefore, measures incorporating adjectives derived from the pleasant/unpleasant dimension may well be useful to the researcher who is attempting to assess the affective components of SWB.

GENERAL MEASURES OF WELL-BEING

In addition to instruments which focus on one or another of the components of SWB, such as life satisfaction or positive affect, some contemporary measures adapt an omnibus approach and include an array of items designed to assess all of the components of SWB. A good example of this type of measure is the Oxford Happiness Inventory (OHI), which has been developed by Michael Argyle and his colleagues (Argyle, Martin & Lu, 1995). The OHI is a 29-item measure which includes items relating to both satisfaction with life and emotional experiences. The OHI correlates strongly with other measures of positive mood and satisfaction, and shows a negative correlation with depression (Argyle et al., 1995). The OHI also has been shown to correlate with personality dimensions such as extraversion and neuroticism. The OHI has demonstrated good internal consistency and test–retest reliability (Argyle et al., 1995), and represents a good, medium length instrument for those wishing to assess all components of SWB with a single measure.

MEASURES OF LOW NEGATIVE AFFECT

Along with measures of life satisfaction, positive affect, and affect balance, measures of negative affect can also be employed in the assessment of SWB. Low scores on measures of depression, anxiety, neuroticism, and other types of negative affect can provide both a complementary index of the respondent's emotional state, and a degree of discriminant validity to the well-being measures as well.

One measure that is frequently used in well-being designs is the Center for Epidemiological Studies Depression Scale (CESD; Radloff, 1977). The 20-item CESD is heavily used as a depression screening device for community work, and its brevity and sensitivity lend themselves to use in a battery of measures intended to assess SWB.

Another commonly used index of low negative affect is the personality trait of neuroticism. Numerous studies have found measures of neuroticism to be strongly negatively correlated with SWB. Many research efforts have included the revised NEO Personality Inventory (NEOPI-R; Costa & McCrae, 1992). The NEOPI-R is a comprehensive 240-item personality inventory which measures five factors of the personality: neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness. In many studies, neuroticism has been shown to be strongly negatively correlated with SWB. In situations where administering a 240-item inventory is not practicable, a shorter version, the 60-item Five Factor Inventory (NEO-FFI; Costa & McCrae, 1992), is also available.

FUTURE PERSPECTIVES

A number of proposals have been offered with regard to the future directions of research on SWB. Diener et al. (1999) proposed the increased use of non-self-report measures in future research designs. They suggest that non-self-report measures provide an important complement to self-report, avoid many of the potential response artefact problems of self-reports, and that non-self-report measures often tap into different aspects of well-being from traditional self-report measures. Also, the same researchers have urged that future investigators create more sophisticated research designs, such as longitudinal, cross-cultural, experience-sampling method, and experimental designs (Diener et al., 1999). Designs appropriate for the application of causal modelling methodologies would be particularly useful in helping to disentangle the numerous correlational relations

which have been demonstrated between SWB and other variables.

Diener (2000) proposed that researchers work toward a 'national index of SWB' (p. 40). He suggests that surveys, utilizing experience-sampling methods and including nationally representative samples, could be used to compile a national index, which in turn could provide important insights into the circumstances under which citizens of various countries experience an optimal sense of SWB. Such an index could provide information to both policy-makers and individuals alike, informing their choices in terms of implications for SWB.

Assessment of SWB has evolved considerably in the past 25 years. Simple survey designs, often including only a one-item measure, have given way to much more complex instruments and strategies. Important advances have been made in the area of non-self-report measures and in the complexity of techniques used for statistical analysis. The next 25 years should see the development of techniques and databases that allow us to come much closer to definitive assessments of SWB.

CONCLUSIONS

A wide array of instruments and methodologies are available to researchers interested in the assessment of well-being. The available self-report instruments vary significantly in terms of their length, psychometric qualities, and appropriateness for various age groups of respondents. In addition, a number of non-self-report assessment techniques are available as alternatives to self-report measures. As is true with any form of psychological assessment, potential users of well-being assessment instruments must be mindful of a number of threats to the validity of their data, and take care in developing their research designs in order to minimize potential contamination of their results. The references provided in this entry should provide the reader with a good general overview of well-being assessment as it is currently being conducted, as well as some important issues for future research.

WISDOM

INTRODUCTION

A first approach to the definition of wisdom from a psychological perspective is its treatment in dictionaries. The major German historical dictionary, for instance, defined wisdom as 'insight and knowledge about oneself and the world ... and sound judgement in the case of difficult life problems'. Similarly, the Oxford Dictionary includes in its definition of wisdom: 'Good judgement and advice in difficult and uncertain matters of life.'

In a next step, psychologists further specified the content and formal properties of wisdom-related phenomena. These initial efforts for the most part were theoretical and speculative. G. Stanley Hall in 1922, for example, associated wisdom with the emergence of a meditative attitude, philosophic calmness, impartiality, and the desire to draw moral lessons that emerge in later adulthood. Furthermore, writers emphasized that wisdom involves the search for the moderate course between extremes, a dynamic between knowledge and doubt, a sufficient detachment from the problem at hand, and a well-balanced coordination of emotion, motivation, and thought. In line with dictionary definitions, such writings refer to wisdom as knowledge about the human condition at its frontier, knowledge about the most difficult questions of the meaning and conduct of life, and knowledge about the uncertainties of life, about what cannot be known and how to deal with that limited knowledge (for an overview see Kramer, 2000; Staudinger, 1999; Sternberg, 1990).

Wisdom certainly is a phenomenon rich in history and connotations. Some even argue it is a phenomenon that defies empirical investigation. And certainly the application of scientific methods changes the phenomenon under study. Nevertheless, it seems useful to study and assess wisdom as it may help us to learn more about conditions that facilitate the development and well-balanced integration of human mind and character.

SOME HISTORICAL BACKGROUND TO THE PSYCHOLOGICAL STUDY OF WISDOM

Since the beginning of human culture, wisdom has been viewed as the ideal endpoint of human development. Certainly, the psychological study of wisdom is still rather young compared to its philosophical treatment when considering that the very definition of philosophy is 'love or pursuit of wisdom'. Important to recognize is that the identification of wisdom with individuals (such as wise persons), the predominant approach in psychology, is but one of the ways by which wisdom is instantiated. In fact, in the general historical literature on wisdom, the identification of wisdom with the mind and character of individuals is not the preferred mode of analysis. Wisdom is considered an ideal that is difficult to be fully represented in the isolated individual.

Throughout history, the interest in the topic of wisdom has waxed and waned (Baltes, in press). In the Western world, the question of whether wisdom is divine or human was at the centre of wisdom-related discourse during the Renaissance. An initial conclusion of this debate was reached during the later phases of the Enlightenment. Recently, in conjunction with value pluralism and the need for orientation characteristic of post-modern times, interest in the concept of wisdom has been revived. Finally, archeological-cultural work dealing with the origins of religious and secular bodies of wisdom-related texts in China, India, Egypt, Old Mesopotamia and the like has revealed a cultural and historical invariance with regard to wisdom-related proverbs and tales (Baltes, in press). This relative invariance gives rise to the assumption that concepts such as wisdom with its related body of knowledge and

skills have been culturally selected because of their adaptive value for humankind.

Among one the major reasons for the emergence of the psychological study of wisdom in the late 1970s and early 1980s was the search for the potential of aging or more specifically, the search for domains or, types of intellectual functioning that would not show age-related decline.

IMPLICIT (SUBJECTIVE) THEORIES ABOUT WISDOM AND THEIR ASSESSMENT

Most empirical research on wisdom in psychology, so far, has focused on further elaboration of the definition of wisdom. Moving beyond the dictionary definitions of wisdom, research assessed the nature of everyday beliefs, folk conceptions, or implicit (subjective) theories of wisdom. The pursuit of answers to questions such as What is wisdom?, How is wisdom different from other forms of intelligence?, Which situations require wisdom?, What is a wise act?, What are the characteristics of wise people? have been at the centre of psychological wisdom research during the 1980s (for a review see Staudinger & Baltes, 1994).

Wisdom in these studies is 'assessed' in two ways. Either participants are asked to sort adjectives according to their similarity (Clayton, 1975) or their probablity to co-occur in one person (Sternberg, 1985). Such ratings were subsequently analysed using multidimensional scaling. In other studies, participants were asked to rate items describing a wise person, a non-wise person, and non-relevant characteristics to which degree they reflect their prototype of a wise person (Holliday & Chandler, 1986). These ratings were then entered into a factor analysis. In both cases, the stimulus material (adjectives, items) was developed based on pilot studies in which participants described their concept of a wise person. Characteristics that were mentioned most often during those interviews were subsequently turned into questionnaire items.

From this research on implicit theories of wisdom and wise persons, it is evident that people in Western samples hold fairly clear-cut images of the nature of wisdom. Four findings are especially noteworthy. First, in the minds of people, wisdom seems to be closely related to wise persons and their acts as 'carriers' of wisdom. Second, wise people are expected to combine features of mind and character and balance multiple interests and choices. Third, wisdom carries a very strong interpersonal and social aspect with regard to both its application (advice) and the consensual recognition of its occurrence. Fourth, wisdom exhibits overlap with other related concepts such as intelligence, but in aspects like sagacity, prudence, and the integration of cognition, emotion, and motivation, it also carries unique variance.

EXPLICIT THEORIES AND ASSESSMENT OF WISDOM

A more recent line of empirical psychological inquiry on wisdom addresses the question of how to measure behavioural expressions of wisdom. Within this tradition, three lines of work can be identified (Staudinger & Baltes, 1994): (1) assessment of wisdom as a personality characteristic, (2) assessment of wisdom in the Piagetian tradition of postformal thought, and (3) assessment of wisdom as an individual's problem-solving performance with regard to difficult problems involving the interpretation, conduct, and management of life.

Assessing Wisdom as a Personality Characteristic

Within personality theories, wisdom is usually conceptualized as an advanced if not the final stage of personality development. Wisdom, in this context, is comparable to 'optimal maturity'. A wise person is characterized, for instance, as integrating rather than ignoring or repressing self-related information, by having coordinated opposites, and by having transcended personal agendas and turned to collective or universal issues. The assessment of 'optimal maturity' poses the problem that it is a highly desirable characteristic. Thus, most of the extant operationalizations suffer from the skewed distributions due to social desirability. Walaskay, Whitbourne and Nehrke (1983), and Ryff and Heincke (1983), for example, have undertaken the effort to develop self-report questionnaires based on the Eriksonian notions of personality development, especially integrity or wisdom. Other attempts have used extant personality questionnaires to

assess wisdom, in the sense of self-development and maturity. For instance, Wink and Helson (1997) used a personality measure and open-ended responses to assess practical (i.e. interpersonal skill and interest, insight, clear thinking, reflectiveness, tolerance etc.) and transcendent wisdom (i.e. transcending the personal, recognizing the complexities and limits of knowledge, integrating thought and effort, spiritual depth). More recently, Ardelt (1997) employed Haan's Ego Rating Scale and Block's California Q-sort to operationalize a cognitive, reflective and affective component of wisdom.

Assessing Wisdom as Neopiagetian Form of Mature Thought

Central to Neopiagetian theories of adult thought is the transcendence of the universal truth criterion that characterizes formal logic. This transcendence is common to conceptions such as dialectical, complementary, and relativistic thinking. Such tolerance of multiple truths, that is of ambiguity, has also been mentioned as a crucial feature of wisdom. A number of different approaches all linked to this basic understanding can be distinguished: dialectical thinking, complementary thinking, relativistic thinking, reflective judgement. Usually, these kinds of mature thought are assessed as performances. Thus, participants are asked to respond to a fictitious problem. The answers are subsequently coded according to respective coding schemes reflecting ascending levels of mature thought (e.g. Basseches, 1984; Blanchard-Fields, 1986; Kitchener & Brenner, 1990; Kramer & Woodruff, 1986; Labouvie-Vief, 1980). Reported interrater agreements usually range between 75% and 85%.

Assessing Wisdom as Expert-Level Judgement and Advice in Fundamental and Difficult Life Dilemmas

Besides these measures of wisdom as a personality characteristic, or as a feature of mature thought, there is also work that attempts to assess wisdom-related performance in tasks dealing with the interpretation, conduct, and management of life. This approach is based on lifespan theory, the developmental study of the ageing mind and ageing personality, research on expert systems, and cultural-historical definitions of wisdom (Baltes, Smith & Staudinger, 1992). By integrating these perspectives, wisdom is defined as an expert knowledge system in the fundamental pragmatics of life permitting exceptional insight, judgement, and advice involving complex and uncertain matters of the human condition (Balles et al., 1992).

The body of knowledge and skills associated with wisdom as an expertise in the fundamental pragmatics of life entails insight into the quintessential aspects of the human condition, including its biological finitude and cultural conditioning. Wisdom involves a fine-tuned and well-balanced coordination of cognition, motivation, and emotion. More specifically, wisdom-related knowledge and skills can be characterized by a family of five criteria: (1) rich factual knowledge about life, (2) rich procedural knowledge about life, (3) lifespan contextualism, (4) value relativism, and (5) awareness and management of uncertainty (see Baltes & Staudinger, 2000 for an extensive definition).

To elicit and measure wisdom-related knowledge and skills, in this approach participants are presented with difficult life dilemmas such as the following: 'Imagine someone receives a call from a good friend who tells him/her that he/she can't go on anymore and has decided to commit suicide. What would the person/what would you do and consider in this situation?' Participants are then asked to 'think aloud' about such dilemmas. The five wisdom-related criteria are used to evaluate these protocols. To do so, an expert panel of raters is selected, and extensively trained and calibrated in using the five criteria to evaluate the response protocols. Every rater is trained on only one criterion to avoid halo effects. And always two raters apply the same criterion to establish interrater reliability. Across over 3000 response protocols now the reliabilities of the five criteria range between 0.72 and 0.93. Reliability of the wisdom score averaged across the five criteria even reaches a Cronbach alpha of 0.98. The exact training procedure and the calibration protocols are described and included in the Rater Manual that can be obtained from the author (Staudinger, Smith & Baltes, 1994).

As one indicator of external validity, it was demonstrated that when using this wisdom paradigm to study people who were nominated as wise according to nominators' subjective beliefs about wisdom, it was found that wisdom nominees also received higher wisdom scores than comparable

Table 1. Selected wisdom measures (after Staudinger, 2000)

Theoretical background	Wisdom components/criteria	Assessment format	Reliability[a]	Author
Implicit theory: prototype of a wise person	Sagacity, reasoning ability, learning from ideas and environment, judgement, expeditious use of information, perspicacity	Similarity ratings	$0.89 \leq \alpha \leq 0.97$	Sternberg (1985)
Implicit theory: prototype of a wise person	Interpersonal skills, judgement and communicative skills, social unobtrusiveness, exceptional understanding, general competence	Prototypicality questionnaire	$0.83 \leq \alpha \leq 0.90$	Holliday and Chandler (1986)
Explicit theory: wisdom as personality characteristic	Integrity versus despair	Self-report questionnaire Adult ego-development scale	0.76	Walaskay et al. (1983–84)
Explicit theory: wisdom as personality characteristic	Cognitive, reflective, affective components	Interviewer rating (Haan's ego ratings, California Q-sort)	Ego ratings $0.51 \leq \alpha \leq 0.62$ Q-sort items $0.85 \leq \alpha \leq 0.93$	Ardelt (1997)
Explicit theory: wisdom as personality characteristic	Practical wisdom (interpersonal skills, insight, clear thinking, reflectiveness, tolerance) Transcendent wisdom (transcending the personal, recognition of the limits of knowledge, integration of thought and affect)	17 items of adjective check list Coding of open-ended responses	$0.75 \leq \alpha \leq 0.86$	Wink and Helson (1997)
Explicit theory: wisdom as postformal thought	Relativistic and dialectical thought	Coding of open-ended responses to fictitious problems according to levels of relativistic and dialectical thought	85% and 86% Interrater agreement	Kramer and Woodruff (1986)
Explicit theory: wisdom as expert-level knowledge and judgement in difficult and uncertain matters of life	Rich factual and procedural knowledge, about life, lifespan contextualism, value relativism, awareness and management of uncertainty	Expert raters evaluate open-ended responses to fictitious life problems quality according to 5 wisdom criteria	Individual criteria $0.65 \leq \alpha \leq 0.94$ Overall wisdom $\alpha = 0.98$ rater reliability	Baltes and Staudinger (2000)

[a]Reliabilities refer to scale consistencies or interrater agreements (per cent agreement or Cronbach α).

control samples of various ages and professional backgrounds (Baltes & Staudinger, 2000). Convergent and discriminant validity was established with regard to extant measures of cognitive and personality functioning. In line with the historical wisdom literature, that portrays wisdom as the ideal combination of mind and virtue, it was found that wisdom-related performance was best predicted by measures located at the interface of cognition and personality, such as a judicious cognitive style, creativity, moral reasoning. Neither intelligence nor personality independently of each other made a significant contribution to wisdom-related knowledge and judgement (Staudinger, 1999). Assessment contexts have to be considered as well. It was demonstrated that wisdom-related performance could be enhanced by one standard deviation if participants were asked to bring a partner with whom they discussed the life problem before reflecting by themselves and responding (Staudinger & Baltes, 1996).

FUTURE PERSPECTIVES AND CONCLUSION

The concept of wisdom represents a fruitful topic for psychological research (a selection of wisdom measures is described in Table 1): (1) the study of wisdom emphasizes the search for continued optimization and the further evolution of the human condition, and (2) in a prototypical fashion, it allows for the study of collaboration among cognitive, emotional, and motivational processes. Future research on wisdom will be expanded in at least three ways: (1) the further identification of social and personality factors as well as life processes relevant for the ontogeny of wisdom, (2) further attempts to develop less labour-intensive assessment tools, and (3) gaining better understanding of the interplay between self-related wisdom and wisdom about others.

WORK PERFORMANCE

INTRODUCTION

Assessing the performance of people at work is one of the most relevant topics in organizational life. For a manager it is essential to be able to adequately assess the performance of his/her employees. All decisions regarding promotion, assessing training needs, transfer decisions, or dismissal are (ideally) related to the (relative) success of employees. This evidently stresses the importance of performance assessment.

In this entry, a brief overview will be presented of how work performance is usually assessed in organizations. The aim is neither to be complete nor to go into great detail, but a comprehensive overview will be provided that can be of help for interested practitioners. Those looking for more detail are referred to relevant handbooks. The entry will be concluded with a section discussing recent developments and future perspectives.

JOB ANALYSIS PRECEDES MEASUREMENT OF PERFORMANCE

For most organizations it is imperative to have a good insight into the relative successfulness of their employees. Not only are most HRM decisions based on performance evaluations, but these decisions may also affect the organization's strategic decisions with respect to future investments. Although most managers will intuitively have an idea which of their co-workers is most successful, intuitions are not sufficient for taking important decisions. Managers have to be accountable for their decisions. And employees are becoming increasingly dissatisfied when their performance is not adequately and fairly assessed. Consequently, organizations nowadays put a great interest in having adequate and objective methods for performance measurement in place.

First, it has to be stressed that measuring job performance is not as straightforward as it initially may look. Jobs can be seen as a configuration of tasks and duties which are derived from the division of work within the organization, and therefore also reflect the organizational processes (Roe, 1999). Modern organizations are flexible and dynamic entities that have to deal with a changing and highly competitive environment. In order to adapt to environmental changes, organizations occasionally rearrange and restructure their processes. In many instances jobs within the organization do reflect these changes, which means that the set of tasks and duties within a job may be susceptible to rearrangement. Job content therefore is not a static concept, and thus the performance that is required in a job changes over time as well.

Another implication is that similar job titles may have different contents in various organizations, there may even be a difference in content between similar job titles between organizational departments. The required performance in a job

is highly dependent upon expectations and priorities within the organization. These are the main reasons that there are no universal instruments and tests to measure work performance. Only in very large organizations, such as the Army, and the police force, in which many similar jobs with standard job content can be found, have standard performance tests been developed for specific job components (i.e. physical tests, knowledge or skills tests).

But in most cases we first have to know what the particular job is about, and what people in this organization are expected to do before an individual's performance can be adequately assessed. Or in other words, first it has to be assessed what the 'core elements' of that job are. This implies that a criterion has to be developed on which the decisions can be based.

A job description might be a useful source of information in this respect. However, in those cases where a job description is lacking, or appears to be no longer adequate, a job analysis may be necessary.

Although a job analysis can be carried out for several purposes (*cf.* Algera & Greuter, 1998), the primary aim in this case is to understand what the particular job is about, and what kind of performance is required. This means that it has to be assessed what the critical, or core, elements of the job are. Furthermore, it is necessary to assess what the most important demands are and, of course, to what extent the job incumbent's capacities are addressed (i.e. how hard the person has to work). And in some instances the *effects* that the job demands have on the worker may be taken into account, in particularly when there may be undesirable health implications.

After it has been assessed what the core or critical elements of a job are and what capacities are needed from a worker to carry out this job, a criterion can be developed. This means that it has to be determined what should be regarded as 'good', 'average', or 'bad' performance in that job. An evaluation of performance enables a description of the relative performance strengths and weaknesses within and between workers.

Multiple Criteria

Since a job is likely to have multiple components, or elements, the next question to be answered is whether a multiple criterion should be used, or whether the scores for each component should be combined into a 'composite score'. To answer this question it first has to be decided how the information is going to be used. For reasons of inter- or intra-individual comparison a multiple score might be most useful; however, in many instances a rank order might be necessary. In the latter situation important questions are which of the various sources of information are most important, and how can the information be combined. Sometimes a job analysis has made clear that some areas of performance are very critical to the job, while other elements are less critical. In that case high scores on the critical job elements may compensate a low score on the less critical elements. In other cases a weighing formula may be used. But then again, an extensive discussion should take place in the organization, in order to decide what a valuable worker is, and how the various types of information might reflect this decision.

PERFORMANCE MEASUREMENT

After it has been decided what job elements should be included, i.e. what kind of performance should be measured, one can start thinking about *how* to measure performance on those elements.

There are many ways to conceptualize and operationalize performance measures (Landy & Farr, 1983). Ultimately, organizations are interested in measuring the employee's contribution to the organizational goals. Depending on the individual's hierarchical position in the organization his/her performance may be closer or more distant to the organizational goals. For instance, the performance of the CEO is more closely related to the organization's overall goal than the performance of a worker on the shop floor. This means that depending on the hierarchical position in the organization different performance operationalizations have to be developed (Smith, 1976). On the other hand, the higher one gets up the occupational ladder, the more difficult it is to find objective indicators that can be solely attributed to the individual's behaviour.

Apart from different conceptualizations and operationalizations, there are also different sources of information to be considered. In general, three different kinds of data can be used for performance assessment: objective data,

personnel data, and judgemental data (Guion, 1965; Landy & Farr, 1983).

Objective Data

Objective data refers to production output, results of work behaviour. Traditionally, output data is seen as the most important source for performance assessment. The simplicity of merely counting what the person has achieved is indeed very appealing. However, this simplicity is deceiving. First of all, there are several output measures to be considered: output quantity, output quality, effectiveness, and efficiency. It is evident that the various parameters are not unrelated, although the relation between the various parameters cannot always be easily assessed. A sales person who makes huge sales, but also appears to have a lot of customer complaints (i.e. high quantity, but low quality), may on the longer term not be effective.

Even with respect to efficiency there are two different perspectives: the perspective of the organization and the perspective of the individual. An organization is likely to measure efficiency in terms of output in relation to money, and/or time, or the amount of scrap, while the individual may conceive efficiency primarily in terms of time and effort investment. This means that something which is efficient from the organization's perspective need not necessarily be efficient from the individual's perspective.

Furthermore there are circumstantial factors that are beyond the individual's control, which may have an influence on the individual's production. For instance, when the number of arrests a police officer makes is considered as output measure, the crime rate in his/her precinct is a relevant circumstantial factor that is beyond the individual's control.

The performance of a nurse cannot be measured by merely counting the number of patients that she has been dealing with that day, or that week, or that month. It is evident that the 'quality of the care' should also be included in the assessment. Quality in this respect relates to professional skills and knowledge of the nurse, but also to her interpersonal skills (i.e. being friendly, and being able to comfort patients, etc.). Sometimes the organizational constraints (the number of patients at the ward, available staff) restrict the nurses with respect to how much time they can spend with patients, and thus may have a negative effect on the quality of the care provided, and thus the nurses' performance. These examples illustrate that measuring output is not as simple as it may seem. Other circumstantial factors that may influence the production are: working conditions, and incentive system (*cf.* Landy, 1989).

In order to be sure that the 'count' is reliable a decision has to be made on the measurement interval; this period should be sufficiently long to allow for some fluctuations.

The most important problem with respect to output assessment, however, is that it is increasingly difficult to find good objective measures. Clearly defined jobs with a repetitive work cycle, which could be found in industrial settings, are relatively easy to assess (Shirom, Westman & Melander, 1999). However, since these jobs tend to have negative effects on a worker's mental health and well-being they have increasingly been restructured.

Personnel Data

Personnel files contain all kinds of information with respect to 'organizational behaviour': absenteeism, promotion, disciplinary actions, number of salary increases, accidents etc. This may be a valuable source of information with respect to performance assessment. But then again, organizations first have to decide what they value most in their personnel: do they value the person with a high production quote, or the person who has a record of not being absent over the past 10 years?

Yet again some remarks have to made with respect to the validity of these kinds of information. First of all various studies have shown that organizational registration systems are far from perfect (*cf.* Landy & Farr, 1983; Koslowsky & Dishon-Berkovits, 2001). Much depends on how conscientious information is being registered, and whether this is done uniformly and standardized over all departments in the organization. Absence registration, for instance, appears to be rather problematic. First of all absence has to be categorized in 'excused' and 'unexcused' absence. Secondly, absences might be recorded in number of absences (irregardless of length), or absolute number of days per year.

In addition, absence registration is easier for employees who are expected to check in each day than for employees who are visiting customers and clients. Organizational climate and management style appear to be very important factors in this respect (Bolwijn & Kumpe, 1996). To what extent is the organization's climate focused on 'controlling' rather than 'motivating' people? With increasing flexibility of working times, and tele-work facilities, it is evident that absence registration is getting more difficult. Many companies have recognized that management style should change accordingly.

Other sources of information in personnel files may have different biases. Promotions and salary increases rely heavily on supervisors' judgements (Landy, 1989). Judgemental data is subject to various kinds of perceptual biases (see next section).

In summary, this does not mean that production data, or information in personnel files, cannot be used for assessing a worker's performance. It only illustrates that these type of data have to be used very carefully and that one has to ask first what the validity and reliability of this kind of information might be. A first step must be to establish that there is a clear relation between these sources of information and the elements of the job that have been identified in the job analysis as relevant to the job performance.

Judgemental Data

A major category of information is the judgement of a supervisor or expert. Supervisors are often asked to rate their subordinates' performance. The type of ratings employed varies considerably. They may range from very rough, unstructured evaluations ('Give a quality rating on a scale from 1 to 5') to more structured methods. Unstructured ratings are very unsatisfactory, because it remains unclear how the supervisor's evaluation is related to the worker's behaviour. Heneman (1986) amongst others has demonstrated that supervisory opinions correlate rather low with objective performance data. It is very likely that inter-personal aspects (likes and dislikes) are interfering with supervisory judgements. Extensive research (*cf.* Landy & Rastegary, 1988) has demonstrated that judgemental information is subject to various types of rating errors (i.e. leniency–severity errors, halo errors, central tendency errors) which appear to be very hard to avoid.

The more structured methods contain specific aspects or behavioural categories that can either be ticked to be present, or evaluated on rating scales. These methods represent attempts to come forward with more objective rating methods that might reduce rating errors. Various sorts of these type of instruments are available, i.e. Checklists, Mixed Standard Rating Scales, Behaviourally Anchored Rating Scales (BARS), Behavioural Observation Scales (BOS). Mixed Standard Rating Scales are based upon a procedure in which items are obtained from experts (usually supervisors) which discriminate between good and poor performance. One performance dimension usually is described with three items: representing 'good performance', 'average performance', and 'poor performance'. Evaluation studies indicated that it appears to be very difficult to apply this type of scale, since it triggers a high percentage of inconsistent responses (Prien & Hughes, 1987; Wiersma & Latham, 1986).

In particular, the Behavioural Anchored Rating Scales (Smith & Kendall, 1963) represent attempts to develop unambiguous rating scales with clearly identified behavioural categories.

According to Landy (1989) the results with respect to avoiding rating errors with the BARS approach are rather disappointing. However, since it is a very laborious and time consuming procedure to develop these scales (use of Critical Incidents), the great advantage of the BARS approach may be that more time and effort is devoted to the whole procedure of performance assessment, and therefore may result in a more considerate approach to the problem.

Peer assessment, i.e. performance rating by colleagues, which is sometimes applied in teams, suffers mainly from the same type of problems. For that reason judgemental data have to be treated very carefully.

Table 1 contains an overview of frequently used types of methods.

Work Samples

Sometimes other ways of assessing work performance are used, such as 'work samples'. Work samples are a selection of tasks that exemplify the actual job. A typical example is a 'programming

Table 1. Methods used for performance assessment (*cf.* Landy, 1989)

Output assessment
Production quantity and quality
Efficiency (time, effort)
Behavioural indicators
Absence registration
Disciplinary records
Promotions
Judgemental ratings
Comparison methods
Ranking individuals from high to low
Pair-wise comparison of individuals
Checklists
Containing statements with free format rating
Forced Choice format (with multiple choice options)
Behaviour oriented rating scales
Mixed Standard Rating Scales
Behaviourally Anchored Rating Scales (BARS)
Behavioural Observation Scales (BOS)
Work samples

test' for computer programmers. The great advantage of this approach is that usually a lot of time has been spent on developing a clearly defined set of tasks that are executed under more or less standardized conditions. As can be imagined this enhances comparison between workers, and therefore may provide a reliable and valid assessment of performance. A drawback of this approach is that it is rather time-consuming and laborious to develop and to administer, and therefore very costly. However, when the development is combined with the development of an assessment centre, since there is a high resemblance with assessing an individual's potential, this may have the advantage of 'economy of scale'.

FUTURE PERSPECTIVES AND CONCLUSIONS

Economic changes, like globalization of the economy, have increased economic competition. Organizations are forced to respond to new environmental challenges, and they do that in different ways. A general tendency to rationalize organizational processes, and increased use of information technology, can be observed. At present the core concepts in organizations are 'innovation', and 'productivity improvement'. And although most organizations recognize that competitive success is highly dependent on people and how their skills are used, the progress and development in HRM with respect to performance improvement systems has been rather disappointing (*cf.* Algera & Kleinbeck, 1997). Apart from the Productivity Measurement and Enhancement System (ProMES), developed by Pritchard and others (Pritchard, 1990), most attention has been devoted to technical and organizational processes. ProMES is an intervention technique primarily focusing on people. The technique is based on goal-setting and feedback techniques (see Locke & Latham, 1990; Naylor, Pritchard & Ilgen, 1980) that aim to enhance the performance of organizational units. The basic characteristics of ProMES are to develop performance indicators, using a bottom-up design methodology for key result areas (products) that can be controlled by the work group. Feedback then is given periodically to the group. This might help the group to adjust their work processes and thus to improve their performance.

The success of this approach is dependent on the success of developing adequate performance indicators for the organizational units. These usually are indicators of a higher aggregation level, than individual performance indicators. When people are working together, and the final result is highly determined by successful co-operation of the team members, it is very difficult to assess the value of the contribution of an individual, in particular when interdependency between team members is high. The issue of 'ownership' of performance is very hard to resolve. Usually the performance of the unit, or group, is considered to be the result of a group process, of which the individual's contribution is an indispensable part. Assessing the performance of the individual is like assessing the individual's contribution to the group process, which means focusing on assessing the person's role in the group, using concepts like 'co-operative behaviour'.

At the same time modern management styles are focusing on motivating people rather than control, by making use of goal setting theories (Management by Objectives). When goals have been clearly defined and mutually agreed upon by the supervisor on the one hand and the group, or individual, on the other hand, performance measurement is a matter of assessing to what

degree these goals are obtained. This approach acknowledges that there are various strategies that may lead to the same result. The choice of strategy is usually left to the job incumbent(s), although there may be more or less 'organizational standards' to tackle certain problems. This type of approach usually applies to highly qualified professionals (i.e. consultancy).

The issues of 'ownership of performance' also applies to some extent to situations in which people are part of large scale man–machine systems, or where people have to supervise continuous processes (nuclear powerplant, chemical processes, aeroplane pilots). Generally speaking the increasing dependency on technology in many jobs makes it difficult to distinguish the individual's contribution from the total 'system performance'. In those cases the focus is on how people have behaved during 'system performance', i.e. did they follow the safety instructions adequately?, and how do they perform when certain scenarios are being trained in a simulator?

Most western economies have changed from an 'industrial' to a 'service oriented' economy in the past decades. This means that in many jobs the emphasis is no longer on production of goods, but on services that have to be rendered. While goods are tangible and usually produced for consumption at a later time, 'services' are not tangible and production and consumption very often coincide. Concepts like 'client friendliness' and 'service orientation' require particular behavioural styles or 'scripts', and may even require workers to display particular kinds of emotions. In particular, when the company wants to propagate a particular atmosphere, or climate (i.e. 'safety': cabin crew in aeroplanes, staff in McDonalds' restaurants have to radiate that they are part of a 'happy family') (Briner, 1999).

In these type of jobs the behaviour and emotions displayed are part of the 'production process', and performance assessment boils down to rating to what extent behaviour and emotions have been adequately displayed.

And finally, a recent development concerns the fact that increasingly work is being organized in projects, which is being assigned to a team. Team members are then going through the whole 'life cycle' of a project, which means that roles change according to the life cycle of the project. This means that jobs tend to be more flexible with respect to job content, and less predefined. Organizations, therefore, nowadays focus much more on 'competence management' (i.e. making sure that staff do have the required skills and knowledge). Because in modern organizations 'success' seems to be the only criterion.
